The adequacy of a properly designated surrogate is usually assumed but should be questioned in two situations. The first is when the surrogate acts in contrast to the patient’s known wishes. Anyone who knows that the surrogate’s directions conflict with the patient’s expressed wishes has an obligation to work with the surrogate to come to a treatment decision more in keeping with the patient’s wishes or to seek outside assistance from the hospital ethics committee or the hospital’s legal department. The second situation occurs when there is doubt about the surrogate’s competence, specifically his or her ability to retain and process information. Again, the ethics committee or the risk management department can be of help in this situation. An important study by Schneiderman et al.¹⁷ demonstrated the value of ethics consultation for ICU patients. In that randomized controlled trial, patients receiving an ethics consultation had shorter ICU and hospital stays as well as a decrease in the use of “nonbeneficial treatments.” This study has led to a call in the literature for more frequent utilization of ethics consultations in the ICU.¹⁸⁻²⁰

FUTILITY

It is often said that “it is futile to define futility,” and this has never been truer than in the current era of medical care. Many diseases that were

once thought to be untreatable are becoming treatable, and diseases with high mortality rates are seeing a decline. It is now common for ICUs to have patients who would have been considered too old or too sick to warrant critical care decades ago. As more of these patients go on to survive the ICU, the boundaries of medical futility get pushed back even farther.

There are many definitions put forth for the term *medically futile*, but most prove inadequate for practical use. The term has been generally used to describe either a patient who simply could not be kept alive (i.e., refractory shock) or a patient in whom death was inevitable in the near future (i.e., advanced cancer). The term *terminally ill* probably better describes the second situation. Nevertheless, these concepts have often been invoked as a justification for limiting lifesaving interventions or denying admission to the ICU. However, this has become problematic. With modern medical interventions such as extracorporeal membrane oxygenation and others that can support vital organ functions, there are fewer times when physicians cannot keep a patient alive. Additionally, as patients with advanced illnesses are increasingly treated in ICUs with the goal of only a few more weeks or days of life, it becomes clear that one person’s definition of *terminally ill* may not be the same for another.

In 2015, several key professional societies (American Thoracic Society, American Association of Critical Care Nurses, American College of Chest Physicians, European Society for Intensive Care Medicine, and Society of Critical Care Medicine) jointly produced and published a statement addressing conflicts of this nature. Notably, the authors chose to avoid using the word *futility* whenever possible, given its subjective nature, and instead use the wording *requests for inappropriate care* to describe situations in which patients or family request care that the physicians feel is of no benefit based on poor prognosis. The statement made several recommendations for physicians addressing such requests.

First, institutions should try to prevent intractable treatment conflicts through proactive communication and early involvement of expert consultants. The term *potentially inappropriate* should be used, rather than *futile*, to describe treatments that have some chance of accomplishing the effect sought by the patient, but clinicians believe that competing ethical considerations justify not providing them. If there is disagreement, clinicians should explain and advocate for the treatment plan they believe is appropriate. Conflicts regarding potentially inappropriate treatments that remain intractable despite intensive communication and negotiation should be managed by a fair process of conflict resolution; this process should include hospital review, attempts to find a willing provider at another institution, and opportunity for external review of decisions. Finally, when time pressures make it infeasible to complete all steps of the conflict resolution process and clinicians have a high degree of certainty that the requested treatment is outside accepted practice, they should seek procedural oversight to the extent allowed by the clinical situation and need not provide the requested treatment.

The group further recommended that the use of the term *futile* should be restricted to the rare situations in which surrogates request interventions that simply cannot accomplish their intended physiologic goal. Clinicians should not provide futile interventions. The medical profession should lead public engagement efforts and advocate for policies and legislation about when life-prolonging technologies should not be used.²¹

In summary, ethics in critical care are founded on the same four primary directives common to all disciplines of medicine. Critical care decision making presents special challenges because these decisions often involve the life or death of patients who are unable to participate in the decision-making process. Although the balance between physician and patient responsibility for decision making may vary across cultures, the primary directive for physicians to act in the best interest of their patients is universal.

KEY POINTS

1. Ethics in medical care is based on four fundamental principles: beneficence, nonmaleficence, autonomy, and justice.
2. In the United States, competent patients have the right to make their own decisions about health care.
3. The process of making known one's wishes regarding future care is called *advance care planning*.
4. In the absence of an advance directive, a surrogate decision maker attempts to make medical decisions for a patient using substituted judgment. When no specific information is available about a patient, decision makers apply a "reasonable-person" standard and sometimes resort to a "best-interest" standard.
5. Discussions about advance directives should be rooted in the patient's values and goals for medical care, as well as the appropriateness of specific interventions.
6. Shared decision making is a process that combines patient autonomy and physician judgment.

Brain death is a legal term that is defined in most countries as the irreversible cessation of functioning of the entire brain, including the brainstem. The diagnosis of brain death by neurologic criteria based on the current medical guidelines is a combination of clinical, radiographic, and laboratory data. After certain prerequisites, three essential components are necessary for this determination: (1) irreversible coma due to a known proximate cause; (2) the absence of brainstem reflexes; and (3) apnea. In select patients, ancillary testing may be necessary to supplement these clinical findings.

LEGAL AND MEDICAL DEFINITION

Currently, no standardized definition exists internationally for the term *brain death*. Within the United States, the legal basis for this definition originated from the 1981 Uniform Determination of Death Act (UDDA), which states that “death” can be defined as an “irreversible cessation of all functions of the entire brain, including the brainstem.” However, even this definition has been modified by some states with various amendments.

The medical definition and guidelines for the determination of brain death are also inconsistent internationally. In 2010, the American Academy of Neurology published updated practice parameters for the determination of brain death.¹ In 2014, a summary was published outlining the development of international guidelines for the determination of death with the phrase *cessation of neurologic function* being used in lieu of *brain death* or *brainstem death*.² Until these legal and medical terms are more uniformly defined, healthcare providers should be knowledgeable of the local laws, guidelines, and institutional regulations prior to the determination of brain death in a patient.

PREREQUISITES

Determination of brain death begins with establishing an irreversible and proximate cause for coma in a patient with continued cardiac function on mechanical ventilation. The irreversibility and proximate causes are established through a combination of the history of present illness, clinical examination findings, radiologic imaging, and laboratory data. The patient’s history and/or CNS radiology should be suggestive of a mechanism of injury to the brain that may lead to complete cessation of brain function. The gamut may include circulatory arrest with the absence of cerebral perfusion to a penetrating injury to the skull or a severe CNS infection with global cerebral edema with herniation. The patient’s clinical examination with no sedative agents should be that of a comatose patient who is defined as having eyes closed and no appropriate interaction to external environmental stimuli. Hypothermia (defined as a core body temperature below 36°C), CNS depressant agents, and neuromuscular blocking agents may obfuscate the clinical examination and need to be systematically excluded. Furthermore, severe electrolyte or endocrine abnormalities may also impact a patient’s mental status and need to be corrected before the diagnosis of coma.

COMA

The examination shows that the patient’s eyes are not held open voluntarily and that no movements are made to verbal or noxious stimuli.

Standard points of noxious stimulation include nail bed, supraorbital, or temporomandibular pressure.

Absence of Peripheral Motor and Sensory Responses

Noxious stimuli in the form of nail bed pressure or muscle pinching should produce no grimacing or withdrawal of the arms and legs. Occasionally, spinally mediated reflexes may remain intact. Differentiating spinally mediated reflexes from retrained motor responses due to cortical activity can be difficult at times and require neurologic expertise.

ABSENCE OF BRAINSTEM REFLEXES

Pupillary Response (Cranial Nerve II)

Pupillary responsiveness should be assessed with a bright flashlight. An ophthalmoscope can be used for magnification to assess for a subtle pupillary response. The pupils are usually round or oval and in mid-position (4–6 mm in diameter). Dilated pupils may suggest intact spinal sympathetic pathways or the release of stored norepinephrine from presynaptic terminals in the orbit. Infrared pupillometry may detect subtle pupillary responsiveness that may not be visible by the examiner.

Assessment of Eye Movements (Cranial Nerves III, VI, VIII)

Cervico-ocular Reflexes (“Doll’s-Eyes Maneuver”)

This maneuver can be performed only after a cervical spinal injury has been excluded. With the patient’s eyelids held open, the head is rapidly turned 90 degrees from midline to the right and the left. If the patient is intubated, the endotracheal tube should be moved with the patient’s head to avoid laryngeal damage or unplanned extubation. The term *doll’s eyes* refers to the expected conjugate horizontal movement of the eyes in the direction opposite to the head movement. This reflexive movement will only occur if the frontal cortex is not providing any input, such as in a comatose patient with intact brainstem reflexes. The absence of eye movements in a comatose patient during head movement is consistent with either upper brainstem dysfunction or a diagnosis of brain death.

Vestibulo-ocular Reflexes (“Cold Calorics”)

Once the cervico-ocular reflexes are determined to be absent, or in circumstances in which these reflexes cannot be tested due to cervical spine instability, the vestibulo-ocular reflexes should be assessed using cold calorics. First, the external auditory canal should be examined to ensure the absence of an obstruction. Given the clinical implications of diagnosing brain death, the presence of a tympanic membrane perforation should not preclude cold caloric testing. The patient’s head of the bed should be raised to 30 degrees. Ice-cold water (the authors use 60 mL) should be placed in a syringe and instilled into the ear while the patient’s eyelids are held open. The amount of water is less important than its temperature; the goal is to depress the temperature of the internal auditory canal. In a comatose patient with intact brainstem reflexes, the eyes should deviate toward the side of the cold water

stimulus. The absence of eye movements is present in a patient who is brain dead. The eyes should be examined for 1 minute after the ice water irrigation. After 5 minutes, the procedure should be repeated in the opposite ear.

Facial Sensation (Cranial Nerve V) and Motor Response (Cranial Nerve VII)

Reflexes involving the cranial nerves V and VII need to be absent before the diagnosis of brain death can be made. The corneal reflex can be assessed by placing a gentle stimulus across the cornea of each eye individually to assess for a blink response. This can be accomplished with a wisp of cotton; however, we prefer a drop of saline to prevent the development of corneal abrasions, which may preclude tissue donation. A jaw jerk can also be assessed by the examiner striking his or her finger (CN VII) placed on the chin to assess for jaw closure (CN V). The absence of a grimace response to the noxious stimulus of the supraorbital ridge or temporomandibular joint should also be tested.

Gag and Cough Reflexes (Cranial Nerves IX, X)

The gag response can be difficult to determine in patients with an endotracheal tube in place. Furthermore, the absence of a normal gag reflex in a significant proportion of healthy subjects renders this test less than useful in a comatose patient. Rather, a cough in response to deep endotracheal suctioning should be evaluated. The absence of a cough response is required for a determination of death by neurologic criteria.

■ APNEA TESTING

After meeting the criteria above, the examiner should proceed with apnea testing to fulfill the diagnosis of brain death. Due to the potential need for frequent arterial blood gases and hypotension during the apnea challenge, the authors place an arterial catheter if one is not already in place. The patient's systolic blood pressure should be maintained >100 mm Hg with adequate intravascular volume repletion and vasoactive agents if needed. The patient should be oxygenated with FiO_2 of 1.0 for at least 10 minutes to obtain a $\text{PaO}_2 > 200$ mm Hg. Longer periods of preoxygenation may be required, but apneic oxygenation should be provided as described in the next paragraph.³

Although the actual trigger for breathing during the apnea test is a decrease in the arterial pH, the test has traditionally been based on the rise of the PaCO_2 . The patient should be disconnected from the ventilator to prevent the false interpretation of artifactual breathing on the ventilator. An oxygen insufflation catheter should be inserted into the endotracheal tube at the level of the carina with the delivery of 100% oxygen at 6 L/minute to provide apneic oxygenation. Patients with poor baseline oxygenation can be placed on 10 cm of continuous positive airway pressure or an appropriate level to optimize baseline oxygenation. The patient's chest wall is closely watched for chest expansion, clavicle elevation, and abdominal excursion. Assuming a normal baseline PaCO_2 (35 to 40 mm Hg), the maximal respiratory drive is believed to occur at a PaCO_2 of 60 mm Hg. If an arterial blood gas shows a PaCO_2 of 60 mm Hg or greater with continued apnea, the diagnosis of brain death is met. Alternatively, an increase in PaCO_2 by 20 mm Hg also meets the criterion.

With an expected PaCO_2 increase of 3 to 6 mm Hg per minute, a target PaCO_2 of 60 mm Hg should occur within 8 minutes after discontinuation from the ventilator. Occasionally, it may take longer to establish this cutoff. The rate of CO_2 production may be affected by the patient's core body temperature and hemodynamics. Since pH is the main determinant of respiratory drive, an equivalent change in the arterial pH may be more reliable than a change in PaCO_2 . The pH should primarily be used in patients with an abnormal baseline PaCO_2 , such as those with underlying lung disease.

In the event the apnea challenge cannot be completed due to cardiac arrhythmias, worsening hypotension, or arterial desaturation, an ancillary test must be performed.

■ ANCILLARY TESTING

An ancillary test must be conducted to declare brain death if the apnea challenge cannot be performed or if uncertainty exists regarding the reliability of parts of the neurologic examination. The validity of these tests, however, remains to be determined.⁴ In several countries, ancillary testing is required by law. In the United States, the need for this type of testing is left to the discretion of the physician.⁵

Cerebral Angiography

Cerebral angiography remains the gold standard to assess intracranial blood flow; however, specific radiographic criteria to define brain death are lacking. The absence of intracranial flow on angiography at the level of entry of the carotid and vertebral artery to the skull has been suggested as being consistent with brain death. The presence of contrast in the external carotid circulation should be present to ensure an appropriate contrast injection. However, in upward of 30% of brain dead patients, there was proximal opacification of the intracranial arteries, with none having deep venous drainage.⁶

Computed Tomography Angiography (CTA)

The utility of CTA as an ancillary test to support brain death remains an issue of debate. In two systematic reviews, the sensitivity and specificity of CTA varied depending upon whether the arterial or venous phase of imaging was used.^{7,8} The sensitivity for brain death seems to be the highest (99%) with the absence of opacification of the internal cerebral veins.

Transcranial Doppler Ultrasonography

Transcranial Doppler ultrasonography (TCD) can be used to assess cerebral blood flow at the bedside, particularly in patients who are too unstable for a conventional angiography or CTA. A distinct pattern of oscillating flow or systolic spikes is typically seen on TCD. Occasionally, an absence of flow is also noted. However, caution must be taken since upward of 10% of patients may have thicker temporal bone windows that do not allow adequate insonation. Two systematic reviews suggest that TCDs have $>85\%$ sensitivity and $>95\%$ specificity; however, these values have a wide range, likely due to the operative dependent nature of the procedure.^{7,9} Nevertheless, TCDs may be helpful in deciding the optimal time to send an unstable patient for ancillary brain death testing.¹⁰

Radionuclide Imaging

Both planar scintigraphy and/or single photon emission computed tomography (SPECT) are utilized in the ancillary testing for brain death. Either of the radioisotopes Tc 99m hexamethylpropyleneamine oxime (HMPAO) or Tc 99m ethylene cysteine diethyl ester (ECD) may be used. The absence of radioisotope uptake into the brain parenchyma is consistent with absent intracranial blood flow and brain death. In a recent systematic review, planar imaging was found to have a sensitivity of 77.8% and specificity of 100% while SPECT was found to have a sensitivity of 90.1% and specificity of 100%.¹¹ As with other ancillary tests, "false-negative" cases for brain death have been reported in the literature.

Electroencephalography

The presence of electrocerebral silence according to published guidelines on electroencephalography (EEG) may be consistent with death by neurologic criteria.¹² The EEG will be affected by the same

confounding factors as the physical examination, such as hypothermia and sedative drugs. Furthermore, electrical activity that is frequently found in an ICU may cause artifacts on an EEG. Several contemporary series of patients have shown a minimal discrepancy between a clinical diagnosis of brain death and EEG findings. Limiting factors may include availability and technical expertise.

Other Tests

Experience with magnetic resonance imaging remains limited and cannot be recommended at this time. Somatosensory evoked potentials (SSEP) may be absent due to severe drug intoxication or hypothermia and should not be used for this purpose.¹³

KEY POINTS

1. Healthcare providers should understand the local laws and regulations regarding the determination of death by neurologic criteria.
2. After certain prerequisites are met, three essential components are necessary to determine death by neurologic criteria: irreversible coma or unresponsiveness, the absence of brainstem reflexes, and apnea.
3. In patients in whom an apnea challenge cannot be completed due to the development of clinical instability, ancillary testing must be performed.
4. Sensitivity and specificity of the various ancillary testing are variable, and the use of specific tests is largely determined by local practice and expertise.

The intensive care unit (ICU) has evolved into a complex environment with multiple professionals practicing together to provide patient care. Technology and care options for critically ill patients have progressed, resulting in improved patient outcomes. While these advances benefit patients, they add to the complexity of care and knowledge needed by critical care providers. The aging population has further strained the healthcare system, creating a greater demand for critical care services. Thus, because of these changes, teamwork is an essential practice when providing care in the current ICU environment.

This chapter will address teamwork in critical care, components of effective teamwork, the impact of teamwork on patient outcomes, strategies to build effective teamwork, and barriers to teamwork in critical care.

THE IMPORTANCE OF TEAMWORK IN CRITICAL CARE

Several factors challenge the achievement of good teamwork in the ICU. Patients admitted to the hospital today have a higher acuity, yet due to cost constraints, there is an increased need for critical care beds and throughput; they are being cared for with shorter lengths of stay (LOS). With an emphasis on using the best and current evidence to guide practice, growth in critical care research makes keeping up with best practices difficult. Critical care practice occurs in a fast-paced environment of constant change in patient census, patient condition, staffing, and available resources, which can breed chaos. Increased oversight by regulators and third-party payers also affects practice, as caregivers struggle to observe fiscal restraint with scarce resources, without compromising quality of care. Clinicians must be able to individualize care, represent the patient's best interest, support family needs, achieve high satisfaction scores, and resolve complex ethical issues. These factors can breed stress, distress, or conflict. Moral distress, posttraumatic stress symptoms, depression, and burnout are all commonly found in critical care clinicians.¹

Healthcare regulatory agencies, commissions, and professional organizations have increased emphasis on the importance of collaboration to achieve quality outcomes. The Society of Critical Care Medicine (SCCM) has focused on delivering the right care, right now. They advocate the delivery of care by an integrated team of dedicated experts who learn, implement, measure, and improve it. Recognition of the importance of teamwork and collaborative practice extends all the way to the education of health professionals. The Interprofessional Education Collaborative (IPEC) published an expert report in 2011 outlining the importance of interprofessionalism and defined core competencies, one of which was teams and teamwork.² Nursing and Pharmacy serve as exemplars with the largest number of actionable skills in their accreditation standards.³

Leaders are gaining appreciation for how organizational structures and processes affect patient outcomes and the importance of highly functional teams. They are creating systems that allow teams to function at the highest level to reduce costs and improve patient outcomes. Successful hospitals will be those that can attract, train, and retain expert team members. Entry-level team members will more likely stay in an environment where they experience meaningful work and thrive within effective teams. This is one strategy to maintain team competence and reduce costly turnover. Top hospitals will build environments

with top-notch teamwork and an intolerance of poor performance and that is supportive of team members who vocalize concerns.

COMPONENTS OF EFFECTIVE TEAMWORK

Broadly, *teamwork* is defined as working well together to accomplish a common goal. Important components include communication, competence, trust, cooperation, coordination, respect, accountability, conflict resolution, and shared decision making.

Historically, healthcare professionals have practiced as individuals, demonstrating autonomy in their respective field of practice supported by its own body of research. ICU patients require multifaceted interventions by an interdisciplinary team of experts. This process requires moving away from isolated practice toward collaborative practice with other healthcare providers. Regularly scheduled interaction among the interdisciplinary team focused on patient-centric goals can foster greater collaboration and communication and can optimize patient outcomes. Through the exchange of ideas and expertise, practitioners become familiar with the nature and scope of one another's practice and are able to assess individual competence. This can build trust and promote the understanding of the unique contributions of team members and their interdependence for providing care. Focusing on the common goal to provide the best possible care for patients is key to reducing team conflict.⁴⁻⁶

Over time, trust and open communication promote respect. Team members begin to appreciate each other's skills, knowledge, and judgment. In collaborative practice, responsibility is shared, so that goal setting and decision making occur jointly.

Being a good team player is a key ingredient to a team's success. Given the obligation to provide the best care for our patients, every team member has the responsibility to make an optimal contribution, speaking up whenever his or her input could be helpful, and listening actively to others' input, while maintaining an open mind. Mutual support among the team (encouraging expression of ideas and positive professional communication) is important to build confidence and perceived value to the team. These actions can lead to collective intellectual capital by the team and potentiate clinical effectiveness.

Team leadership is also critical to performance. Good leaders generate two-way trust, respect, and communication. They have vision, self-confidence, enthusiasm, tolerance, and a commitment to excellence. They are organized and prepared, fulfill commitments, inspire shared missions, grow new leaders, model behaviors, challenge processes, tolerate ambiguity, and remain calm. Leaders who think out loud help novices develop their teamwork skills and competence. Leaders also set the tone for the function of the group and must demonstrate respect for the collective contribution of its members. Team members must ask for help when needed and express concerns without retribution in an environment that is psychologically safe. To have high-quality ICU teamwork, each team member should possess leadership characteristics, as team leadership often changes, depending on the issue at hand.

IMPACT OF TEAMWORK ON OUTCOMES

Despite the support for teamwork and the development of an interdisciplinary team model for the care of critically ill patients, research on

the relationship to outcomes is limited.⁷ A literature review on the effectiveness of patient care teams in a variety of healthcare settings found a limited effect on patient outcomes, and the added value of coordination of care was unclear.⁸ However, reports from studies in critical care have demonstrated positive effects.

Teamwork and Patient Safety

ICU patients are highly susceptible to medical errors. Severity of illness, intervention complexity and number, invasive devices, and ICU LOS put critically ill patients at a higher risk for adverse events and errors.⁹⁻¹² One comprehensive review of critical incidents in intensive care showed an increased incidence of adverse events when there was a deficit in nontechnical skills, including elements of teamwork.¹³

Ineffective communication and poor teamwork have been identified as significant contributors to patient errors and critical incidents in the ICU.^{12,14,15} Improved communication may reduce adverse events and errors.^{15,16} In medicine, the focus has been on what should be done with insufficient attention to planning or execution.¹⁰ To effectively carry out any ICU care plan, coordination between disciplines and departments with clear, specific communication about the treatment plan is needed. One initiative to improve teamwork in the ICU involved establishing physician-led multidisciplinary rounds, assessing bed availability daily, and using “bundles” of evidence-based practice care. The results included a significant reduction in nosocomial infections (ventilator-associated pneumonia (VAP), bloodstream and urinary tract infections), adverse events, and the cost of care. A team decision-making culture places the responsibility on the team rather than on the physician, empowering team members to contribute.¹⁷ More recently, multidisciplinary teams have implemented checklists for assessing each patient to improve communication among providers, enhance team knowledge, and better coordinate care.

The Veterans Administration reported improvements in team communication and quality of care after implementing a training program to enhance team performance, satisfaction, and patient outcomes.¹⁴ They credited their debriefing training and process with the avoidance of adverse events of wrong site/wrong procedures, improvements in surgical efficiency, fatigue management, active collaboration among disciplines, nurse job satisfaction and morale, and reduced errors in surgical patients.

Teamwork and Patient Outcomes

Intensivist-led multidisciplinary teams have been espoused as an ideal model for critical care. However, insufficient numbers of trained intensivists exist to meet current or future demands, and a limited number of ICUs have implemented intensivist staffing.^{7,18} Furthermore, outcome studies on intensivist-led care demonstrate mixed findings.^{7,18,19} One large patient cohort study compared the mortality outcomes from hospitals with daily multidisciplinary team rounds with and without intensivist models.⁷ Hospitals with high intensivist staffing and multidisciplinary team care had the most significantly reduced odds ratio of death. Interestingly, hospitals with multidisciplinary care, but low physician staffing, also had significant odds reduction in mortality, reinforcing the idea that patients benefit from care by a multidisciplinary team. Mortality has been significantly reduced in patients with acute lung injury cared for by multidisciplinary teams led by full-time critical care physicians.²⁰ The use of the intensivist-led team model also led to significantly reduced mortality, duration of mechanical ventilation, and rates for VAP in a military setting.²¹ A literature review summarized that the team model for ICU care delivery was associated with reduced mortality, ICU and hospital LOS, and the cost of care.²²

One hospital in Illinois implemented evidence-based bundles of care and a multidisciplinary daily goals rounding tool, resulting in decreased ICU LOS, improved protocol compliance, reduced VAP, bloodstream infections, falls, and pressure ulcers in surgical ICU

patients.²³ Cheung et al. did not find improved outcomes when the team met on a weekly basis and concluded that the meetings were too infrequent to impact patient outcomes.²⁴ Research indicates that teamwork can also improve timely discharge from the ICU through the coordination of efforts.²⁵

The ability to achieve patient goals in the ICU is impacted by team leadership and the management skills of attending physicians.²⁶ Written daily goals in the ICU improve communication about care expectations and the follow-through on treatment plans. Failure to complete treatment plans has been recognized as a key contributor to errors and increased ICU LOS.^{10,26} Fostering teamwork to accomplish daily goals can improve care effectiveness and patient safety.

Multidisciplinary teams developed to respond to shock in non-trauma patients resulted in decreased time to treatment, intensivist arrival, and admission to the ICU.²⁷ This led to a significant reduction in mortality and improved patient outcomes.

Teamwork and Team Outcomes

Attitudes and perceptions of the teamwork quality vary widely among institutions, units, individuals, clinicians, and professions. Communication, a key component of teamwork, has been associated with job satisfaction. Studies have shown a difference in perception about communication among practice disciplines in critical care.^{4,15,28-31} Nurses report a lower quality of communication with physicians than physicians report. In one survey of critical care nurses, only 33% ranked the quality of collaboration and communication with physicians highly as compared to 73% of physicians.⁴ The degree of open communication among ICU team members was correlated with a better understanding of patient care goals. A study by Huang²⁹ found that physicians, leadership, and nursing directors tended to overestimate nurses' attitudes on teamwork climate and working conditions. Weinberg³⁰ found that the quality of medical resident communication with nurses was dependent on a nurse's degree of cooperation and congeniality. The level of trust in information communicated also was dependent on the perception of nurse competence and the ability to relay relevant information in a timely manner. Nearly all physicians reported instances of poor communication with nurses. They did not see it as a threat to patient care, because they thought the nurses' role was to simply follow orders, suggesting these medical residents did not view nurses as colleagues and collaborators. Differing perceptions between nurses and physicians also exist regarding dying patients in the ICU.³¹ Nurses reported more moral distress and less collaboration than physicians. Nurses perceived the ethical environment as more negative and were less satisfied with the quality of patient care than were the attending physicians. Their evaluation of quality of care was strongly related to the perception of collaboration among disciplines. In critical care, the multidisciplinary team members are dependent on each other to accomplish the complex needs of patients, and all are accountable for the outcomes achieved. The strides being made in interprofessional health care education may help to reshape these paradigms.

When teamwork increases the efficiency of care, an increased sense of accomplishment can occur.^{32,33} Research has shown that nurses preferred communicating with attending physicians over first-year residents and valued shared understanding and open, accurate communication.³⁴ The more experienced nurses required effective communication with experienced physicians. Another study showed that nurse-to-physician communication was a significant predictor of nurse job satisfaction and the quality of the practice environment.³⁵ The degree of workplace empowerment and perceived quality of the environment was significantly related to communication between nurses and physicians.³⁶⁻³⁷ When a higher level of nurse-physician communication was reported, medication errors were reduced,³⁶ and when the timeliness of communication improved, the prevalence of pressure ulcers decreased.³⁷ This further reinforces the notion that good communication may lead to a sense of team ownership of the unit and patients and may translate into better overall care.

Finally, daily multidisciplinary rounds led by a hospitalist medical director paired with a nurse practitioner resulted in improved physician-to-nurse collaboration, particularly with residents. The nurse practitioner facilitated coordination of patient care and nurse-physician communication.³⁸

STRATEGIES TO ESTABLISH BETTER TEAMWORK

Since teamwork is so important for practice in the ICU, it is vital that steps be taken to implement team structures and processes that can help build teamwork in critical care. Models to develop strong teamwork have developed from industries with high risk for errors, including aviation, the military, and nuclear power. In these industries, effective teamwork is an important mechanism used to maintain safety, reduce errors, and increase efficiencies.^{39,40} Team members use specific processes for communication, leadership, coordination, and decision making to achieve positive team performance outcomes.

Although healthcare is different from these industries, lessons can be learned to improve teamwork in critical care.³⁹ Applicable strategies include standardizing work processes and using checklists to ensure patients are consistently receiving care based upon the best current scientific evidence and to improve teamwork skills, collaborative engagement, and communication. All interdisciplinary team members should be able to speak up when they identify potential patient safety hazards, and mechanisms should be developed to openly identify areas of high risk for errors and harm. A blame-free culture encourages team members to recognize, report, and thus minimize errors and learn from mistakes. Much like in an assembly line, when one team member recognizes the potential for harm, it must be pointed out and managed expeditiously.

Reader et al.⁴⁰ consolidated the research literature of the relationship between teamwork and patient outcomes in critical care. They emphasized that effective teamwork is crucial to provide optimal patient care in the ICU, and good leadership is vital for team interaction and coordination. Four key performance competencies are needed to build effective teams in the ICU: (1) team communication; (2) team coordination; (3); team leadership; and (4) team decision making.

Another strategy to engage ICU interdisciplinary teams is the involvement in quality improvement initiatives.⁴¹ Including key stakeholders from various professions is important for comprehensive team engagement when developing plans for practice improvements. Ongoing behavior modifications may be needed to engage all team members in the change. Good team leaders collaborate with team members to sustain quality efforts and help them through difficulties in adapting to change.

Barriers to Team Performance

Implementing teamwork strategies within healthcare has its challenges. Barriers to implementing a critical care team model can include local customs, hospital patterns, and reluctance to change despite proven benefit.²² Implementation requires a cultural shift. Hierarchic and status differences can present a barrier to team function and the ability of team members to openly contribute to the plan of care if they are not convinced that their input is important.^{28,42}

Another barrier to the intensivist-led team in the ICU is inadequate numbers of qualified physicians trained in critical care.¹⁸ The ability to recruit medical residents into critical care fellowships is challenging, particularly with concerns about financial compensation and the hectic lifestyle. Costs are also associated with implementing the intensivist model.^{18,22} While the absence of intensivist-led leadership presents more difficulty in implementing team models of care, establishing a multidisciplinary team in the ICU is still possible and improves outcomes.⁷

Another obstacle is that working as a team requires team members to forfeit some of their autonomy in practice.²² This may be difficult when team leaders place high value on their ability to independently

orchestrate care. The physician leader must be willing to engage members of the team and establish respect and trust for their contribution to discussion and decision making, as well as to create an environment that welcomes such activity.

Many practitioners in the ICU have not been trained in teamwork activities and are unfamiliar with the nontechnical skills required to perform well on a team.¹³ Individual team members' knowledge, skill, and personality characteristics influence their effectiveness on teams.⁸ One qualitative study showed that the amount of emotional distress that individual members experienced during medical crises impacts the function of the entire team through contagion of anxiety.¹ Another study on team interactions during crises found that in the postcrisis period, nurses were left with significant questions and emotions about the event compared to other team members.⁴³ Potential solutions to these barriers are interdisciplinary team debriefings and feedback sessions immediately after crises, assessing for anxiety and defuse emotional breakdowns during critical interventions. Leaders can evaluate gaps in teamwork competencies, and determine opportunities for team training in safe settings to prepare members emotionally for real events.

Programs Used to Develop Teamwork in the ICU

Programs designed to improve team core competencies and communication skills may be accomplished through experiential team learning. A pediatric ICU provided an interdisciplinary experiential learning day-long program to improve communication skills and relationship abilities when having difficult conversations with family members. The training included videotaped case scenarios, debriefing, and sharing their experiences. This approach resulted in improved communication skills, confidence, perceived preparation, and reduced anxiety.³²

Teamwork skills can be developed to improve the communication between physicians and nurses to improve care at the end of life (EOL).⁴⁴ Studies show that nurses and physicians differ in perspectives and burdens felt with EOL decisions. Strategies to improve communication among caregivers include joint grand rounds, patient care seminars, and interprofessional dialogue regarding EOL care during daily rounds. Teamwork can also be enhanced when multidisciplinary expertise is focused on key patient outcomes. One example was a critical care team that identified factors that interfered with mobility in mechanically ventilated patients.³³ The ICU team developed a strategy for early mobility in ventilated patients and measures to evaluate the effectiveness on patients' functional abilities and long-term outcomes.

Programs to improve patient safety and collaboration in the ICU have been developed using a crew resource management (CRM) approach.⁴² One group identified five key components needed for hospital CRM training: communication, task management, situational awareness, decision making, and leadership.⁴⁵ Program content on interpersonal communication, conflict resolution, and the nonthreatening critique of team performance and methods to improve system processes for care (e.g., using checklists and standardizing handoffs to relate key information, debriefings for patient errors, cross-checking, and ongoing review of patient care plans) can reinforce concepts. Courses like these can prepare team members to actively participate in decision making, voice concerns, and make recommendations for patient care in a constructive manner.

Simulation-based learning is another mechanism for training the team to function under specific circumstances. Team learning in scenario-based simulation exercises allows professionals to learn their roles and practice safely under circumstances outside of stressful clinical settings.

Simulation can be used for education on specific care topics involving teams. Examples include managing septic shock using high-fidelity mannequins and scenario-based videos,⁴⁶ resuscitation and management of acute respiratory failure, airway management, myocardial ischemia, trauma, and shock.⁴⁷ Simulation-based learning can be used

to improve handoff communication and reduce errors in relaying critical information across teams,⁴⁸ build teamwork competencies, and CRM.¹⁴

Multiprofessional Support for Teamwork in Critical Care

Key professional organizations support teamwork enhancements to drive improvements in practice. SCCM promotes an intensivist-led model for care by a team of multidisciplinary experts. Their guidelines for critical care delivery outline characteristics of the multidisciplinary team that support teamwork⁴⁹: medical and nursing directors with authority and coresponsibility for ICU management; collaboration with a team approach across disciplines; using standards, protocols, and guidelines for a consistent approach to care; coordination and communication for all aspects of ICU management; and an emphasis on certification, research, education, ethical issues, and patient advocacy.⁴⁹

The American Association of Critical Care Nurses actively supports teamwork within their healthy work environment initiative. Their website has tools to evaluate and promote teamwork (aacn.org). The Institute for Healthcare Improvement promotes quality improvement with teamwork as a key component in their initiatives, and their website (ihi.org) also has many useful team-building tools. The Agency for Healthcare Research and Quality has a comprehensive, evidence-based program to improve communication and teamwork skills among healthcare professionals called TeamSTEPPS. Information on this comprehensive program is housed on their website (teamstepps.ahrq.gov). Pharmacists have embraced collaborative practice as seen in their combined SCCM/ACCP position paper on critical care pharmacy services. The vast majority of fundamental, desired, and optimal activities uses collaborative practice wording.⁵⁰

EXAMPLES OF TEAMWORK IN CRITICAL CARE

Collaborative Practice Teams

Collaborative practice teams (CPTs) are groups assembled for a particular population to address issues related to clinical practice and outcomes. These teams are interdisciplinary in scope and function. They design initiatives to drive evidence-based practice and improve quality of care. A critical care CPT composition depends on the purpose of the team, patient population, and disciplines directly involved in the care of patients relevant to the team function (e.g., physicians, nurses, respiratory therapists, physical therapists, pharmacists, nutritionists, social workers, clergy, administrators, risk managers, infection control, safety officers, and quality improvement personnel). The goal is to capture expertise from multiple disciplines to improve the delivery of care. Examples of CPT initiatives are the development of disease-specific protocols, care “bundles,” order sets, and performance improvement campaigns. Some teams are formed to manage care for particular situations or patient types, such as medical emergency response teams who respond to calls about acute changes in patient condition outside of the ICU and facilitate timely assessment and treatment of patients to reduce development of further deterioration. Other specialty teams can be developed to assess and manage urgent clinical conditions, including stroke, sepsis,⁴⁶ and shock.²⁷

Daily Interdisciplinary Team Rounds

Daily interdisciplinary rounds on ICU patients enhance patient care.²² Teamwork is involved via discussion of the patient care plan. Daily rounds also provide opportunities to augment CPT initiatives. Communication regarding the plan of care by the team can be facilitated by using a daily goals checklist during rounds.⁵⁰ Team accountability for assignments and goals established during rounds occurs during reviews for completion at day's end. This approach has demonstrated improved team and patient outcomes.^{23,26,51,52}

Krinsky et al. developed a model to increase the implementation of measures to prevent venous thrombosis, VAP, and stress ulcers in ICU patients.⁵³ They integrated evidence-based strategies, a team communication tool, daily prompts in ICU progress notes to assess these complications, and real-time feedback of performance measures to correct behaviors. This model allowed the incorporation of these evidence-based practices using a team-based culture of patient safety.

CONCLUSION

As we struggle to increase patient safety, prevent harm, decrease chaos, and improve outcomes, mechanisms to integrate complex behavior into functional teamwork have become increasingly important. Harmonious and efficient integration of personnel and their respective expertise in the complex critical care environment is key to the delivery of high-quality intensive care. Ideally, care will be coordinated and delivered by a team with a high degree of mutual respect, who values and listens to all contributions, resulting in care that is efficient and timely.

KEY POINTS

1. An emphasis on teamwork to promote collaboration to improve outcomes and reduce costs has increased as the care of the critically ill has become more complex and resources more limited.
2. Barriers to ICU teamwork include increasing patient acuity, rapidly developing evidence-based practice, lack of teamwork competencies and training, insufficient physician-led multidisciplinary teams, increased oversight of critical care delivery, and the stressful nature of intensive care practice.
3. Key skills required for teamwork include communication, competence, trust, cooperation, coordination, respect, accountability, conflict resolution, and shared decision making.
4. With the increased focus on teamwork, several models of teamwork in the critical care environment and resources have become available.
5. Research shows that improved processes in teamwork and communication can lead to improved patient outcomes and healthcare team satisfaction.
6. The interdisciplinary team has an opportunity to partner together to drive quality improvements in the care of the critically ill.

ANNOTATED REFERENCES

Brilli RJ, Spevets A, Branson RD, et al. Critical care delivery in the intensive care unit: defining clinical roles and the best practice model. *Crit Care Med* 2001;29:2007–2019.

This article is the consensus report of two task forces of the SCCM. It represents the work of 31 healthcare professionals and practitioners, including statisticians and representatives from industry, pharmacy, nursing, and respiratory care and physicians who are involved in the practice of critical care. This report suggests that the best practice in critical care is collaborative practice with a multidisciplinary team.

Reader TW, Flin R, Mearns K, et al. Developing a team performance framework for the intensive care unit. *Crit Care Med* 2009;37:1787–1793.

This article summarizes evidence on the relationship between teamwork behaviors and patient outcomes. Skills required for effective team performance are identified. Synthesis of the existing literature yielded a framework organized around three aspects: input, team processes, and output. This framework can be used as a guide to team building in the ICU.

Curtis JR, Cook DJ, Wall RJ, et al. Intensive care unit quality improvement: a “how-to” guide for the interdisciplinary team. *Crit Care Med* 2006;34:211–218.

This article summarizes how a team can work together to accomplish performance improvement initiatives in the ICU. In this article, the systematic steps an interdisciplinary team can take to develop

or enhance quality improvement are summarized. Key roles for team members and leadership are identified.

In the beginning it was all about the art—magicians or medicine men who were thought to have special powers and could cure the sick through communing with a higher power. As societies became more complex and evolved, a more scientific approach began to influence the healing of the sick. Ancient Egypt provides us with one of the first documented pieces of evidence of this transition through the Edwin Smith Papyrus (17th century BC), covering 48 cases examining a variety of traumas to the human body. From here, the art and science of care metastasized many times over (and still today)—sometimes in conflict, but always progressing toward greater treatments, greater therapies ... greater understanding. For the past 50 years, the art and science of medicine have been struggling to come to terms with a new challenge/opportunity, one born out of necessity as therapies became more expensive and complicated. Ideally, the solution should set parameters, demands, and requirements but also provide a dynamic for enabling better use of resources, individual and organizational knowledge, and accelerating the pursuit of excellence. This opportunity, the business of medicine, is an integral part of health care today and in the future, and together with the art and science, is part of a new paradigm. It is time for a new construct—a model for health care that focuses on and weaves together leadership, talented professionals, innovation, reliability, excellence, sustainability, efficiency, effectiveness, and safety.

It is a truism that most performance is average, though often with large variation. But in the context where excellence is the only acceptable performance, average is failure. In the intensive care unit (ICU), where life is extremely fragile, *average* means patients are dying needlessly. The obligation is only excellence every time, for every patient. Those who are willing to make the commitment to strive for world-class performance should read on. There is a dearth of literature that directly addresses how leaders of ICUs can create a system, a culture, that engages the workforce, supports great teamwork, creates an environment for continuous and rapid innovation, astutely develops and deploys strategy, distinctly focuses on holistic patient excellence, and delivers care at the highest possible clinical competency with the greatest effectiveness and efficiency.

Organizations consist of numerous parts, systems, and functions all operating and, ideally but too infrequently, collaborating to produce an end result. Unlike the organs of the human body, in health care delivery, different components often struggle to operate in a coordinated and symbiotic fashion. Systems such as pharmacy, lab billing, ICU, operating room, emergency department, internal medicine, surgery, and graduate medical education programs frequently operate independently without the coordination necessary to produce reliably integrated operations. The parts seem more independent than interdependent, more competitive than cooperative, and more focused on their own efforts rather than on the results of the whole. Whereas each part has to remain viable and effective in order to contribute to the overall goals and purpose of the organization, all parts must operate in harmony for superior performance to be achieved and maintained. Using the Baldrige Performance Excellence Program (BPEP or Baldrige) as a framework (Fig. 180-1), this chapter provides guidance on how to design and manage the ICU to improve patient outcomes and, even more compellingly, to become and remain a role model for ICU care everywhere. The Baldrige framework is elaborate, and a full presentation is beyond the scope of this chapter. A complete guide to the framework can be found at www.baldrige.org.

■ BACKGROUND AND OVERVIEW

The BPEP began in 1987. It was the culmination of the inspiration of business and federal leaders to create a business performance framework and awards program to stimulate excellence, competition, and innovation during a time when the U.S. manufacturing and service industries were losing market share to foreign companies. The end result produced an evolving robust framework based on best practices across seven different but highly interrelated spheres. Organizations that pursue the Baldrige and submit an application can be recognized by the president of the United States for exhibiting role model practices. While there is an award component, most organizations adopt the framework for its demonstrable value rather than the recognition. Organizations around the world have adopted the Baldrige framework for improving organizational performance practices, capabilities, and results. Based on an extensive study of Baldrige applicants in 2011, the benefit-to-cost ratio of 820-to-1 represents cost savings from using the Baldrige framework, plus gains from consumer satisfaction, plus gains to the economy from resources saved. Since health care was added as an industry permitted to apply for the Baldrige Award in 1999, only 19 health care organizations have been recognized.

The Baldrige framework has been validated to guide organizational success at both a macro system level (organization level) and the constituent micro system level (division, service line, department, or unit). ICUs are prime candidates to benefit from application of the Baldrige platform. The fragile patient population requires highly reliable delivery of very precise care around the clock. The environment is complex, with multiple layers of caregivers and diverse technologies and medications, which are lifesaving yet life-threatening if performed improperly and occur simultaneously (e.g., mechanical ventilation, dialysis, and invasive monitoring). The opportunity for error/harm is high, the patients' tolerance for error is marginal, and the cost is huge. Improvement demonstrations (Keystone Project, Institute for Healthcare Improvement [IHI] and Veterans Health Administration [VHA], and New Jersey Hospital Association [NJHA] ICU collaboratives) have demonstrated that ICU patients are suffering unnecessary morbidity and mortality, and improvement in outcomes and cost is possible but requires a systems approach. For example, most U.S. ICUs lack intensivist staff, an intervention associated with a 30% reduction in hospital mortality and costs that has demonstrated improvement in eliminating the preventable deaths of 31,000 people each year from central line-associated bloodstream infections (CLABSI). The need to improve is urgent. Indeed, the Baldrige platform approach can serve to orchestrate improvement in this complex environment. ICU leaders can use the Baldrige framework to improve clinical and economic performance. This framework is goal-directed and measurement driven. Briefly, the Baldrige Health Care Framework is built on four integrated components: organizational profile, 11 core values and concepts, 7 categories of criteria for high performance, and differentiation of high performance versus average performance or scoring guidelines.

Organizational Profile

The first integrated component, the organizational profile, is a brief description of how the organization (or ICU) operates, its customers and their expectations, its primary services, core competencies, the

FIGURE 180-1 ■ Baldrige health care criteria for performance excellence framework: a systems perspective. (Adapted from www.baldrige.org.)

workforce (which includes all paid staff, medical staff, and volunteers) requirements/needs, critical success factors, and key challenges, to name a few.

What differentiates your ICU from the thousands of others? The organizational profile also introduces a new key factor of Core Competence that is defined at an extremely high level of performance compared to its more common definition that is close to a minimal standard. In the Baldrige framework, there are around 20 questions that ask the ICU to identify, with extreme clarity, the important elements that guide the delivery of care.

Eleven Core Values and Concepts

BPEP provides penetrating insight into what is needed to create and sustain a culture that is consistently high performing through the second integrated component comprised of 11 interrelated core values and concepts. They have been validated to be embedded in the beliefs and behaviors (the culture) of high-performing organizations:

1. Systems perspective
2. Visionary leadership
3. Patient-focused excellence
4. Valuing people
5. Organizational agility
6. Focus on success
7. Managing for innovation
8. Management by fact
9. Social responsibility and community health
10. Ethics and transparency
11. Delivering value and results

Seven Categories of Criteria for High Performance

The seven categories of health care criteria for performance excellence, which constitute the third integrated component, serve as the locus of role-model performance. The criteria are presented as a series of questions that ask how an organization's (or unit's) approaches (or methods) to work are designed and managed so that they are systematic (or repeatable), deployed to all locations and internal/external people as appropriate, are continuously improved, aligned with the key areas of

importance to the ICU, and integrated with other processes and systems to effectively deliver care. The criteria present direct actionable guidance by identifying existing strengths and opportunities for improvement. The even greater power lies not in the individual areas but rather in the interplay of the seven categories, which are as follows:

1. Leadership
2. Strategy
3. Customers
4. Measurement, analysis, and knowledge management
5. Workforce
6. Operations
7. Results

Differentiation of High Performance Versus Average Performance or Scoring Guidelines

The scoring guidelines serve as the fourth component of the framework. These four elements are critical to understanding performance, identifying opportunities for improvement and innovation, and achieving sustained excellence. Together, these "ADLI" characteristics differentiate high-performing organizations from average ones in that all work must be:

1. **Approaches** that are systematic (i.e., process or methods that are well ordered and repeatedly done in the way it is designed to be done, demonstrating reliability);
2. **Deployment**: full and complete deployment of the approaches/process/methods is done systematically everywhere it is supposed to be done—all sites, departments, units, and staff;
3. **Learning** to improve what has been fully deployed through measurement and evaluation for effectiveness as part of ongoing cycles of learning, improvement, and/or innovation (i.e., improvement is built into how work is done);
4. **Integration**: all work is aligned to and integrated with key factors such as the mission, the vision, the needs of ICU patients and family members, best evidence-based ICU medicine, ICU department objectives, to name a few; and harmonized with other key ICU/organizational processes and systems to achieve maximum efficiency and effectiveness.

High-performing organizations differentiate the results of their critical success factors from those of lesser organizations based on (1) whether current results are good, (2) how results trend over time (i.e., show consistently beneficial trends, and (3) how trended results compare with best-in-industry (role-model) performance.

How does all this relate to ICUs? ICUs across the country are the beneficiaries of medicine's most advanced techniques and technology serving the most critically ill patients and anxious, if not frightened, families. Yet ICUs struggle with increased complexity, higher costs, the absolute demand for error-free care, cumbersome documentation systems, staffing shortages, decreasing morale and low staff, and inconsistent customer/patient satisfaction and engagement. The human service purpose of ICUs is far too precious for ICU quality to be sub-optimal—a sign of leadership failure. Industry experts must find a road map that is proven to guide the pursuit of sustained excellence. The Baldrige framework is that singular, all-encompassing framework to total organizational and cultural excellence. Anything less than excellence is failure; high reliability in ICU care is not optional.

It is important to remember that the Baldrige program is not an improvement tool like Six Sigma or the Plan-Do-Check-Act (PDCA). Rather, it is a larger framework that provides guidelines and a structure to establish and sustain culture and processes that go *beyond* mere conformance to standards, differing from requirements such as those of The Joint Commission. Baldrige asks fundamental questions that will help lead and guide organizations—and ICUs—toward the highest levels of performance excellence humanly possible. It is how the work should be organized, managed, improved, and innovated. And, whereas the Baldrige framework asks these important questions, the ICU leaders need to provide the answers.

THE BALDRIGE INTENSIVE CARE UNIT

Category 1: Leadership

The leadership category provides insight on how leaders can guide their organizations to high levels of performance. It analyzes how clinical and nonclinical leaders use values, directions, and performance expectations, as well as a focus on patients, other customers, workforce engagement, innovation, and continuous improvement, as vehicles to secure systematic action and sustained excellence. In the Baldrige framework, leadership is not just an organizational chart of positions. It is also a system—a set of leadership behaviors that move and align the organization toward a common purpose with specific goals and objectives. Leadership systems include the formal and informal method of exercising leadership elements such as decision making, communication, setting expectations, organization of work, reward and recognition for high performance, and planning. Using the unit's mission, vision, and values (MVV), the ICU leadership system orchestrates a systematic approach to communicating and deploying key organizational requirements and expectations throughout the entire workforce by providing a single, unifying purpose to all actions that ensure success now and in the future.

The criteria for leadership are instructive as they relate to ICUs and are likely very different from the current approach. Within the ICU, opportunities exist for the leadership team to become a more instructive leadership system (Fig. 180-2) and promote a unit that demonstrates repeatable and fully deployed process across all areas of delivering ICU care. The leadership team ensures consistency of care across boundaries, incorporates and supports continuous cycles of improvement and/or innovation, and strategically aligns with the overall goals and objectives of the hospital.

To illustrate this point, the following example is offered: one ICU used a multidisciplinary leadership group to set and deploy the values, short- and long-term directions, and performance expectations throughout the unit. This team consisted of the intensivist physician leader, functional administrator, and nursing supervisor. The multidis-

ciplinary leadership group used a variety of tools and methods to communicate the values and directions of the unit, such as cascading employee development plans that correlated the high-level ICU goals and objectives such as absolute error-free care down to each employee, and articulating how they contribute to the achievement of those goals. Prior to this process of cascading accountability, the leadership team held four revolving all-ICU-participant meetings to get input from the workforce on key changes, ideas, and needs such as new equipment and guidelines for improving patient safety as they developed the strategic plan. Involvement of the workforce in planning demonstrates a departure from typical strategy processes, which usually live at the senior leader level, and are fostered upon the workforce for their less than enthusiastic or knowledge-based buy-in and engagement.

Consistent with the Baldrige criterion that asks how leaders review performance and translate their reviews into opportunities for continuous breakthrough improvement and innovation, the multidisciplinary leadership group met every month to review performance—using industry-standard metrics such as a balanced scorecard that specifically correlates with strategic goals and objectives designed to stretch performance more acutely toward excellence. For example, the leadership group, through its strategic planning process, identified teamwork and communication as areas for improvement as they related to patient safety and employee engagement. Using a cultural assessment tool to obtain the facts (*management by fact* is a Baldrige core value), it was discovered that over the past year, the ICU had a decrease in nurse satisfaction and an increase in issues identified via a nurse assessment of patient safety. After drill-down sessions with the doctors, nurses, pharmacists, patients, and others, the leadership group learned that communication between the nurses and the physicians was lacking and that patients were suffering—all impacting job satisfaction. In addition, the ICU was experiencing an unprecedented level of staff turnover. As a result, the leadership group added to each employee's job description the requirement to participate in quarterly teamwork and communication training sessions and added key patient high reliability safety indicator(s) to the annual individual evaluations. The intention was to drive accountability farther down to all workforce

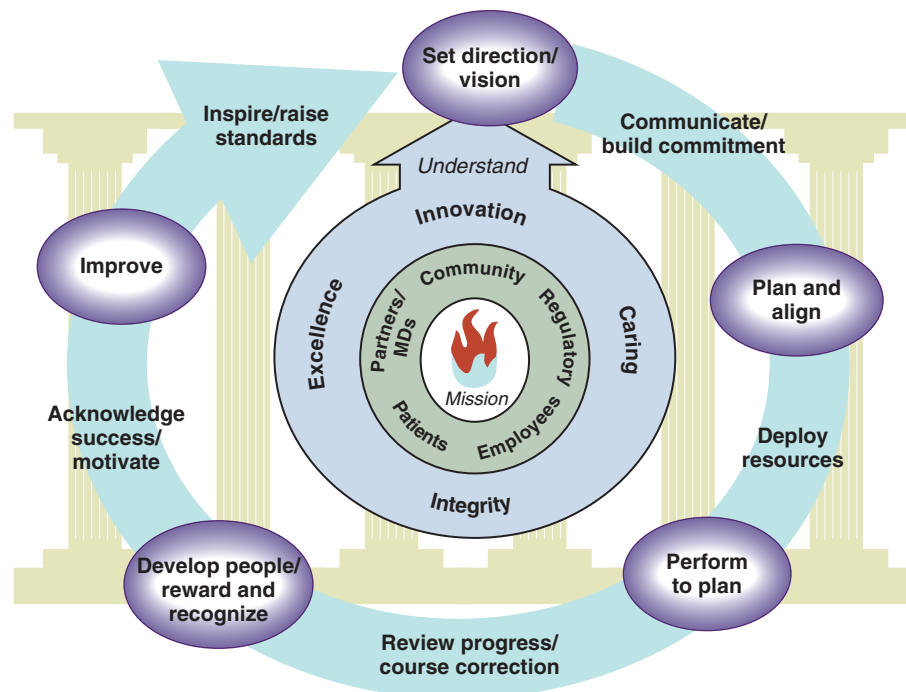

FIGURE 180-2 ■ Example of a leadership system (Sharp Healthcare, San Diego, CA). (Adapted from 2007 National Baldrige Application.)

members and link to new rewards and recognition initiatives. This process became systematic—repeatable—and the leadership team sought feedback from the workforce on the process's effectiveness and ideas of how to improve it even further.

In addition to the individual goal requirements, the leadership group set a unit goal to increase employee engagement, learning, and rates of improvement and innovation. Critical to this goal was the creation of improvement teams that were supported by the hospital and ICU leadership in terms of time, finances, and other resources. Through the strategic planning process, the multidisciplinary leadership group learned that the staff felt their efforts to change and improve patient care consumed large amounts of time and that these efforts were neither supported nor appreciated by senior leadership. The stress level and complexity of the ICU environment contributed to turnover and dissatisfaction. The leadership group realized that the creation of conduits for the staff to change, innovate, and improve processes that decreased complexity and raised satisfaction levels needed to occur rapidly. The leadership group put together a multidisciplinary action team, using a Lean/Six Sigma method of improvement, to design systems that would empower and motivate the staff to change and innovate. These were then presented to the multidisciplinary leadership group for implementation and tracking of performance.

Category 2: Strategy

This category deals with how the ICU develops its strategic objectives and more detailed action plans and how they are deployed throughout the unit. The ICU leadership system incorporates internal and external inputs to create short- and longer term strategy in the form of strategic objectives, action plans, and goals for the unit. These goals must align with the MVV of the unit and hospital to communicate a constancy of purpose. When the leadership team meets to discuss the strategic plan, it must consider how the strategic plan is developed, communicated, prioritized, benchmarked, and measured. In addition, it should consider how the ICU's strategic planning process incorporates the following:

- Customer (patient, family) and key stakeholder needs and expectations
- The competitive environment and collaborative opportunities within the community
- Technology and other innovations that might have transformational impact on ICU services
- Strengths and weaknesses of the unit
- Changes in the local, regional, or national environment
- Alignment with the unit's core competencies, the ICU's greatest area of expertise and capabilities that are of strategic importance and are frequently challenging for competitors or suppliers to imitate. They present a competitive advantage.
- Ability to execute the plans and long-term sustainability

To illustrate this concept, the following example is offered: ICU leaders organize a plan that answers the basic question, "How will we ensure the success of the ICU now and in the future? Together with the hospital's strategy, the ICU's MVV drive the entire decision-making and strategic planning process. While aligning with the MVV and other specifics such as an environmental assessment (data on the external and internal environment), a strengths, weaknesses, opportunities, and threats (SWOT) analysis, and past ICU performance, the leadership group uses the yearly strategic planning process to identify strategic advantages and challenges, the unit's key objectives and goals, key customer groups and segments, measurement strategies, workforce-related issues, opportunities to innovate, and action plans needed to achieve the strategic objectives. The strategic plan is not static; it is organic and constantly evolves and leaders remain agile as new opportunities and challenges emerge on the unit. The leadership group is always doing strategic planning, and the annual plan document serves as a foundation for beginning to accomplish excellence. The strategic plan creates clarity, purpose, and a vision of where the ICU is headed and how they plan to arrive at that destination.

Once the plan has been completed, it is cascaded down to all ICU staff for implementation with clear linkages to their role and contributions to the work. It gives meaning to their job. It answers the why question of why do we do this work? Each year, the overall planning process is updated according to key customer feedback, ICU performance analysis, organizational positioning, competitive data, and industry standards and trends. Integral to this process is the implementation of actionable measures of the strategic objectives. For example, part of this ICU's mission is "to simultaneously eliminate all preventable harm to the patient, while providing exceptional care." Bloodstream infections were identified by data analysis as one area of preventable risk for cardiac patients. After the multidisciplinary leadership group discovered that bloodstream infection was an area of concern (and benchmarked their results against local competitors, national averages, and best in class), its prevention became a key strategic objective for the following year, and action plans were designed to create systems that would lower and move to eliminate these infections. The plans included education and training on an infection bundle, staff empowerment tools to monitor conformance to standards, transparently monitoring and reporting infection rates, and further teamwork training, particularly around the use of an infection checklist.

Crucial to this process is how the ICU communicates the strategic plan to the entire unit. It is not only the leadership group that should know this plan; in high-performing organizations, every employee knows what's going on and how they fit in to the overall work. In our example, each employee was issued a cascade plan to guide work processes, goal setting, and professional development. These cascade plans list and strategically link and align the objectives of the hospital, the ICU, and the individual. The cascade plan is used quarterly as a performance assessment tool (Table 180-1).

All together, strategy development and implementation are important parts of an organization's approach to excellence and sustaining excellence. A plan is just that—a set of steps to achieve an end. The real challenge is in effectively executing the plan every month, week, day, and minute and remaining opportunistic and agile in the midst of changing circumstances.

Category 3: Customers

These criteria address how the ICU engages patients and stakeholders (1) to better serve their needs through specific voice of the customer methods, (2) to build relationships, and (3) to improve services based on the expectations of the identified customer groups. *Customer engagement* refers to patient/customer commitment to an organization's services. It is a much higher determination of relationship compared to mere satisfaction. At the ICU level, no patient or family member really wants to be loyal to an ICU, since it means their health is at serious risk, yet as leaders and managers, there is an obligation for the organization to deliver care at such amazing levels of distinction that if a patient or family member had to be admitted to the ICU, he or she would only want your organization and, in particular, your unit. Segmentation is a key element in this section of the framework. Most ICUs can predict with some relative confidence the types of patients who occupy their beds, and through segmentation of this population, it is possible to customize each aspect of care delivery to improve outcomes and service and eliminate inefficiencies and inconsistencies in experience.

The challenge for ICU leadership is to determine how to ensure consistency of practice in the midst of this urgency and complexity. Key to this effort is the need for the ICU to identify the types of patients (and their families) for whom they typically provide services, segment them according to needs and expectations, and then tailor health care services to meet their particular needs. The concept of "stages of relationship" in the framework is an important consideration for increasing customer engagement. It suggests that leaders think about the various phases of a patient's and family's interaction with the ICU—from admission, to their stay, to transferring to another unit, for example. During these stages, the needs of the patient and family

TABLE 180-1 Sample of Cascading Organizational Objectives**STRATEGIC OBJECTIVES TO INDIVIDUAL ACCOUNTABILITY**

| STRATEGIC AREA | ORGANIZATIONAL STRATEGIC OBJECTIVE | ICU ACTION PLAN LINK TO STRATEGIC OBJECTIVE | ATTENDING PLAN LINK TO ICU PLAN | MANAGER PLAN LINK TO ICU PLAN | BEDSIDE NURSE PLAN LINK TO ICU PLAN | OVERALL ORGANIZATIONAL METRIC |
|-------------------------|------------------------------------|---|--|---|--|--|
| Clinical patient safety | Lower mortality rates. | Adopt CUSP program. Reduce decubitus ulcers. | Participate in culture of safety survey and one improvement project. | Participate in culture of safety survey, and monitor ulcer bundle compliance. | Participate in culture of safety survey, and identify ulcers at earliest stages. | Mortality rate Decubitus ulcer rate |
| Clinical patient safety | Eliminate infections. | Implement evidence-based infection bundles. | Learn, implement, and innovate infection bundles. | Monitor compliance on infection bundles. | Learn and use safety checklist. | Number of infections |
| Workforce | Be the best place to work. | Be the best unit in the hospital. | Attend two teamwork training sessions. | Attend two teamwork training sessions. | Attend two teamwork training sessions. | Workforce engagement scores Top Box |
| Customer | Be the best place to receive care. | Achieve the highest customer engagement scores in the hospital. | Implement family rounds. | Implement morning staff huddles, covering one key service standard a week. | Implement "key words at key times" process. | Customer engagement scores Top Box |
| Operational | Reduce system waste by 5%. | Run Lean projects to reduce length of stay. | Lead or participate on a Lean waste reduction team. | Lead or participate in a Lean waste reduction team. | Identify three opportunities to reduce waste in daily work. | Length of stay |
| Financial | Increase financial sustainability. | Increase operating margin. | Complete medical record notes on time. | Maintain supplies, salaries, and other expenses within current year budget. | Achieve 100% accuracy on charge entry and documentation. | Operating margin |
| Innovation | Transform the delivery of care. | Implement ideas program. | Develop five "big ideas" for the ICU. | Teach, reinforce, and monitor the ideas program. | Submit 10 new ideas. | Number of nationally recognized best practices |

Action plans are the tactics to accomplish an objective. CUSP, comprehensive unit-based safety program; ICU, intensive care unit.

From www.safetyresearch.jhu.edu/QSR/.

members might change, signaling the need to alter certain systems and processes. In doing so, the ICU is better positioned to secure and/or increase their engagement at each stage of their relationship with the ICU and better manage its limited resources.

For example, cardiac ICUs see a variety of patient types, yet most can be broken into two large segments: short-term and long-term patients. Within these segments are subgroups of patients ranging from those recovering from coronary artery bypass grafts to those requiring ventricular assist devices. Care plans can be implemented that are customized to deliver the best outcomes for each of these groups and are consistent with the unit's goals and directions. Patients requiring ventricular assist devices tend to require prolonged ICU stays. Therefore, the ICU team develops a plan to coordinate resources efficiently to meet the needs and expectations of this long-term patient cohort, such as how a room is set up to accommodate family members. Similarly, the short-term patient cohort can be segmented according to needs and expectations to better use the unit's resources. For example, medications most frequently used by the short-term patient group can be trended over time for predictability, and the evidence shows that

just six medications actually account for over 85% of all medications given to these patients. These medications can then be located in a locked cart at the patient's bedside, reducing the need for the nurse to use the highly complex medication dispensing and delivery process, which at times is frustrating to patients awaiting their medications. Use of data to track and predict trends in medication usage can allow unit staff to work more effectively and better serve the needs of patients.

Medically, the talented professionals working in the ICU know what is best for the patient; however, the question remains: What do the patient and family need and expect in order to have a positive experience that *includes the family*, whose needs are too often unmet? To some, this might seem of limited significance, considering the condition of most ICU patients. Yet there should be a way to determine these additional customer/patient requirements, and ICUs should incorporate systems for gathering this information and apply it to the delivery of care in real time. For instance, one approach might be to follow up on the ICU experience by having a nurse from the ICU speak with the patient or family after transfer to the step-down unit. The information gained could be analyzed for trends and fed into a

prioritization system for planning and implementation. It could also become part of the transfer documentation so the incoming staff knows the patient's needs without having to query the family another time. For example, by talking to families, it was identified that they desired the type of seating and lighting that could allow them to take a brief nap between visits to their loved ones. The ICU can also proactively use quarterly focus groups and information gleaned from medical associations to elicit key knowledge to design care and even innovate care that is both medically optimal and patient driven.

In 2002, the Institute of Medicine recommended six tenets of the 21st century health care system. One of these is a focus on patient-centered care and involvement of the patient and family in the care plan. It is vital to the success of the ICU to make concerted efforts to identify the key requirements of their patients by segment and then build care plans around those requirements in each stage of relationship. Without this input, it is unlikely a given ICU will reach levels of world-class performance and excellence. And, it cannot know or take action on how the ICU performs in comparison to the ICUs of competitors. To ensure sustainability, the ICU must always identify, incorporate, and amend services with the changing needs of all their customers. Through leadership, role model behavior, and appropriate and effective communication, the workforce will feel empowered to incorporate the information gathered from the different patient segments and deliver care that is deemed appropriate based on the medical evidence and the wants and needs of the patient.

Category 4: Measurement, Analysis, and Knowledge Management

Now that the ICU has refined its leadership system, created its strategic goals and objectives, and gathered and used key patient data to set action plans and work processes, a robust and clear structure of measurement and analysis is needed to evaluate the effectiveness of the strategy and key health care systems and processes.

How does one measure performance, analyze performance, and use benchmarking information to support fact-based decision making, drive innovation, and ensure sustainability? How does one make certain everyone in the chain of delivery of ICU care has all the necessary information when they need it, and that it is in the correct form and accurate so the next clinical decision, diagnostic test, or treatment can be carried out in a timely manner? How does one make certain

that clinical information in the electronic health record is available rapidly on request, provides a complete holistic picture given the life-and-death reality of intensive care? And, in the interest of achieving high ICU performance, how does one make certain the sharing of knowledge (the great ideas, experiences, and talents of the workforce) is a cherished part of the culture and is actively (versus passively) managed?

In addition to measurement, this section addresses how the ICU manages knowledge, transfers information to staff and patients, and shares best practices within and outside the unit. The criteria ask us to think innovatively about how we measure performance, the importance of relationship among all outcomes (e.g., issues with the workforce could impact clinical outcomes), process and outcome measures, and what is the true measure of mission and vision achievement. Further, the criteria challenge us to create a structure for ensuring the measures are valid, ensuring the data are accurate and of high quality, reviewing performance, identifying opportunities for improvement/innovation, and translating them into priorities.

The ICU's key measures cascade down from the hospital's overall goals, which in this example fall into six areas of focus: clinical performance, customer engagement, workforce engagement, operational performance, population health, and financial performance (Table 180-2). During the strategic planning process, the leadership group, using input from the workforce, identified three or four leading indicators within each area that directly predicted the achievement of the key objectives and goals of the unit. These were then validated through a set of criteria asking certain questions:

1. Are the data collectible?
2. Do relevant, preferably high-performance comparisons exist?
3. Are the data understandable/translatable to action?
4. Does the measure provide actionable, credible, reliable, reproducible, and timely information?

Once validated, the measures become part of the unit's balanced scorecard, to indicate performance across a balanced set of areas of importance. Measures then are "drilled down" for each employee to create a line-of-sight from the big goals to their specific work. For instance, one of the unit's measures is zero infections, and subsequently the environmental staff who serviced the unit had a goal and a tracking measure of patient infections by room as one measure among others of a fully comprehensive approach and ICU cultural imperative to doing everything every time in ways that prevented the spread of

TABLE 180-2 Sample Key Measures of Intensive Care Unit Performance

| STRATEGIC OBJECTIVES | METRIC | 1-YEAR GOAL | 3- TO 5-YEAR GOAL |
|------------------------|--|---|--|
| Clinical excellence | Decubitus ulcers Infections Use of evidence for sepsis patients Use of ventilator bundle Rate of adverse drug events | Reduce 20% Zero bloodstream infections 100% of patients 100% of patients Zero | Reduce an additional 30% Maintain at zero Develop quality measures for transfusion 100% of patients Zero |
| Workforce excellence | Positive staff engagement (% of Top Box) | Improve 30% | Achieve above top 10% compared nationally |
| Customer excellence | Positive patient engagement (% of Top Box) | Improve 30% | Achieve above top 10% compared nationally |
| Operational excellence | Canceled surgery Length of stay Rate of diverted cases Use of agency nurses | Zero Reduce 30% Reduce 50% Zero | Maintain at zero Reduce an additional 20% Zero Zero |
| Financial excellence | Operating margin Drug costs | 5% Reduce 30% | 7% (reinvest in quality) Reduce an additional 15% |
| Innovation excellence | Number of clinical and/or process innovations implemented | Three new processes implemented | Twenty new processes implemented internally and three that impact nationally |

Top Box refers to counting only the highest box on a Likert Scale. For example, when measuring customer engagement on a 5-point scale, only those who rate the ICU as "excellent" are counted, not an average of those who rate "very good" and "excellent." Top Box is a more difficult assessment.

infections. Their job, and the communication of the leadership, is not just cleaning—rather it is helping reduce infections and improve patient safety.

As another example, the leadership group set a goal of zero catheter-related infections, a widely accepted target in health care. Data reviewed at the monthly leadership meeting revealed the incidence of bloodstream infections to be not only inconsistent but also generally increasing and the rate of infection to be not only well above that of best-in-class but also above previous performance levels. Achieving the agreed-upon and vital target of zero infections seemed impossible. The leadership group identified this as an opportunity for improvement and elected to convene a multidisciplinary team to reduce the number of bloodstream infections. This group replicated the high-reliability approach used in the Michigan Keystone ICU study that virtually eliminated these infections throughout the state.¹ The bloodstream infection reduction team used the weekly infection control data collected and implemented interventions such as a catheter checklist on line carts, empowering the nurses to stop catheter placement if physicians did not comply with the checklist items. In addition to investigating every infection as a defect, they also met to discuss and analyze their successes, asking how did we manage infection-free cases, to focus on successes and not just failures as input into infection-free training on teamwork and communication for the nurses and physicians. Continuous cycles of improvement were implemented, and the bloodstream infection trend data demonstrated a progressive reduction. Work processes related to catheter insertions became standardized in the unit and were ultimately communicated through the organization via a new policy and monitored for adherence.

It is also important for ICU leaders to consider how they manage the knowledge assets contained within the ICU. Baldrige defines knowledge assets as “the accumulated intellectual resources ... it’s the knowledge possessed by your organization and employees in the form of information, ideas, learning, understanding, memory, insights, cognitive and technical skills, and capabilities.” ICU leaders who are committed not only to high performance but also to distinctive performance should learn how to manage the unique knowledge of their units. A mechanism to maintain this knowledge, communicate it, and share it across the organization is vital to an ICU moving toward high performance.

In health care, all stakeholders—physicians, nurses, and administration—often have legitimate concerns about the validity of performance measures. Category 4 attempts to mitigate these concerns by developing a system of aligned measures, relevant comparisons to gauge results, a structure for reviewing these metrics, prioritizing them into opportunities for improvement and innovation, and establishing a robust framework for liberalizing data and information as transparent to all key stakeholders in the care process.

Category 5: Workforce

In health care, the term *workforce* traditionally means all paid individuals, yet Baldrige takes a different view—a more holistic approach—defining the workforce through the eyes of the patient. For decades physicians were considered customers by hospital leadership: treat physicians as customers and they will fill our beds. This is an outdated view that is no longer even minimally acceptable. In high-performing health care settings, doctors (paid or volunteer staff) are considered part of the workforce (sans certain benefits); engaged in planning, work system design, and budgetary authority. Specifically, Baldrige states *workforce* “refers to the people actively involved in accomplishing the work ... it includes your permanent, temporary, part-time personnel, independent practitioners, volunteers, and health profession students.” Through the eyes of the patient, the doctor is a member of the workforce in making my care, he/she is a leader of that workforce with regard to what is decided, ordered, and performed.

Similar to Category 3 (customer engagement), this section brings to the forefront the importance of an engaged workforce, meaning

the extent to which all members demonstrate a “commitment, both emotional and intellectual, to accomplishing the work, the Mission, and Vision of the organization” (or ICU). Here, leaders and staff are asked to determine the key factors that drive the engagement of a segmented ICU workforce, how to create a culture of high performance in the unit, learning and development opportunities, career progression, and hiring and organizing a workforce dedicated to achieving excellence.

All organizational and ICU results are lagging indicators of how well the workforce performs. ICUs that do not emphasize maintaining a workforce that is skilled, trained, engaged, motivated, and safe should expect undistinguished performance. The paragraphs that follow offer some insight into a few of the key components of this category.

In an ICU, different members of the workforce funnel in and out of the unit on a daily basis—from lab technicians, to various physicians, to dietitians, to nurses, to pharmacists, and so on. In a teaching hospital setting, the number is obviously greater with residents and students of numerous types. Managing the styles, personalities, and roles each of these groups play in the care delivery process in a highly complex area like the ICU is an extraordinary challenge that often gets overlooked and is left to traditional models of health care interactions. Each unit has its own culture, and leaders—together with the workforce—need to first identify the desired attributes of the culture and needs of the workforce, and then develop an approach to fostering and reinforcing the desired culture. For instance, in one ICU, one of the cultural expectations was that each employee should innovate at least one process each year, measured via their annual staff evaluations. In addition, the unit created two awards to celebrate the best innovations: “The Super Innovator” and “The Game Changer,” which were shared throughout the organization and published in the quarterly hospital newsletter. By adding this expectation, monitoring it, and creating reward systems, the ICU leadership demonstrated a commitment to aligning the goals of the unit with the actions of the workforce.

A work design that allows the workforce to achieve the highest levels of performance, while promoting collaboration, initiative, empowerment, and innovation, has to be the goal if patients are the true customers. So the question remains: How is this accomplished? Using the Baldrige criteria in their entirety is one way of achieving this end. The framework involves a set of characteristics of high-performing organizations inclusive of thematic linkages throughout all processes of an ICU. Specifically, how is work performed so that it is systematic (repeatable based on how it is designed to be done), fully deployed, continuously improved, aligned with other care provided to the patient, and also ensures the work is aligned with the MVV and strategic objectives of the ICU?

Taking this a step further and using the example of bloodstream infections, we can examine how teamwork and communication have helped reduce, if not totally eliminate, catheter-related infections through alignment of goals and objectives. After the leadership group identified bloodstream infections as a continuing strategic priority and funneled it through a working team, concerns arose regarding the nursing staff’s ability to intervene when physicians broke standard protocol for catheter insertion. A number of nurses reported situations in which they had tried to intervene despite the emphasis on patient safety and the widespread knowledge that these infections can be substantially eliminated, only to have the physician ignore their observations and proceed with central catheter placement that did not follow proper protocol, thus exposing the patient to increased risk for a bloodstream infection. Using this feedback, the leadership group insisted on full deployment of best practice and deployed multidisciplinary training on the tools and methodologies of teamwork and communication, such as situational awareness and safety briefings. In addition, the leadership group wrote a new policy that required physicians to stop and listen to the nursing staff if a potential for a bloodstream infection was observed or be subject to corrective actions. The result of this endeavor empowered the nursing staff to be supported

and feel comfortable intervening when patient safety might be at risk and reinforce the established safe practice.

Category 6: Operations

Up to this point, we have addressed ICU performance related to its leadership, strategic planning, patient relationships and engagement, performance review, access to information and knowledge, and workforce engagement—all in the context of high performance. Now we address the bottom line: How do we “make” excellent ICU care? It is time to think differently about how ICU care delivers value. The Baldrige criteria focus on delivering value in every step of health care design and delivery, improvement, and ongoing management. The criteria in category 6 provide ICU leaders with a structure and discipline to think through their delivery processes to ensure that all steps are value-adding, as measured by effective diagnosis and elimination of disease (to the extent possible), exceeding the expectations of all stakeholders, and capitalizing on the ICU core competencies. What care delivery management system can ensure that value is always delivered, outcomes do not suffer, performance levels do not decline, and safety prevails? Process management is the focal point for ICU high performance. It provides guidance on how the ICU identifies, designs, improves and innovates, transforms, and manages its health care services to achieve results when trended over time to approach, demonstrate, or sustain world-class performance. It obligates ICU leaders to clarify how these processes are continuously improved to achieve better performance, improve cycle times, reduce waste, reduce variability, and, of course, improve clinical outcomes. These criteria for performance excellence are key to avoiding being just average.

For example, it is important for the ICU leadership group to create work processes that deliver care based on the needs of all ICU constituents—patients, physicians, nurses, pharmacists, payers, and so forth—and align with the goals and objectives of the unit. The question needs to be asked: How do our processes ensure that we deliver value for those we serve, and how do we know we have been successful? Using this mantra as a guide, the leadership group in our ICU example aligned the work processes with the unit to continuously meet the expectations of each ICU customer segment in each stage of their relationship with us throughout the ICU experience. This involved a number of approaches; however, the ultimate deliverable was a system of work designed to achieve the key requirements identified in the ICU strategic plan. Data indicated that the lack of clarity around a given patient care plan and the role of each member of the care team were causing increased errors and longer stays. Using the goal of reducing harm and improving teamwork and communication among the unit's health care professionals (as stated in the strategic plan), the leadership group tested and implemented an evidence-based checklist developed by Peter Pronovost and colleagues that incorporates a multidisciplinary team approach to making rounds.² During these rounds, a daily goals sheet is used to communicate the care plan for the particular patient to the multidisciplinary team, consisting of physicians, nurses, pharmacists, and others. The use of this checklist over time led to a reduction in length of stay and adverse drug events, and both nurse and physician teamwork and satisfaction scores have improved. This mechanism is guided by several criteria in this Baldrige category dealing with the inclusion of patient expectations, testing to prevent errors, and achieving better performance by reducing variation in care. Unexplained and avoidable variation in care is one of the principal causes of failure in health care process and outcomes.

Health care is too full of waste, errors, and inefficient processes that do not add value. Over the past few years, an increasing number of improvement methodologies have made their way to health care, such as Lean Thinking, the Toyota Production System, High Reliability Methods, and in the 1990s, PDCA, to name a few. All of these tools offer opportunities to improve ICU effectiveness and value and are commonly in active use in high-performing organizations using the Baldrige framework, which asks how an ICU reduces variability,

improves outcomes, and shares learning to drive innovation. Yet, the Baldrige criteria go further and help an organization hold the gains from these types of improvement tools. One of the major challenges facing hospitals and ICUs is something called “diminishing returns.” This concept, somewhat akin to economics, dictates that after an organization exerts enormous amounts of time, energy, and other resources to improving a process, the gains often eventually erode back to previous levels of performance, primarily due to a culture that is not set up to sustain improvements. One notable exception was the Keystone ICU project in which reductions in bloodstream infections throughout the state of Michigan were sustained for over 3 years, largely thanks to efforts to improve culture, something akin to the cultural implications when successfully adopting the Baldrige framework. Through the seven integrated Baldrige criteria, it is possible to reduce the likelihood of diminishing returns and effectively address an issue and be able to focus on other initiatives while not worrying about losing ground.

The complexity of ICU care demands that its leaders employ methods of excellence at a greater intensity compared with other health care venues. Application of the Baldrige criteria, designed to enable any operating unit to achieve distinctive performance, is greatest in the ICU. Otherwise, we are left largely with less effective methods of management and improvement that have demonstrated, thus far, the inability to fully leverage the extraordinary talent that resides within. In such places, the care and the experience in delivering it remain woefully suboptimal.

Category 7: Health Care Results

In the end, the results of a given ICU are the ultimate measure of its performance. Now that the ICU has defined its mission, vision, and values, identified what its distinctive core competency is (or should be), set strategic objectives, become relentlessly patient-focused, established methods to ensure that all ICU staff have the required information and knowledge, and created work processes that inspire the staff and add value to the patient, it is paramount that the ICU use the data it collects (on its key objectives) as a feedback loop or mechanism to continuously review its performance and achieve the identified goals outlined in the strategic plan. Selecting measures and having a system or process for making the data actionable and understandable (such as a balanced scorecard) allow the ICU to constantly implement corrective strategies when an area for improvement is identified. This category does not deal with the deployment of key processes; rather, and quite simply, it involves the unit's ability to effectively align its mission, vision, and values and meet its stated goals and objectives as compared with both the competition and best-in-class benchmarks. Comparative performance is set at best-in-class: how else will the ICU leadership and workforce know that it is a role model for ICU care everywhere?

CONCLUSION

ICUs are places of emotion, extraordinary science, compassion, and sometimes high drama in the conflict between disease and injury, the will to live and the hopes of loved ones. Optimally, they are designed to enable the uniquely talented professionals who dedicate their careers to healing at the highest levels. Yet experience has proved with alarming frequency that the enormous and sometimes even heroic good that is accomplished is marred by what could or should have been done. Patients and their families enter our ICUs trusting that we will do what is needed, correctly and with compassion. There is only one standard of care acceptable—no excuses are permitted. The Baldrige program, the nation's formally adopted approach to excellence, is not just another improvement tool. Rather, it is a framework of systematic elements that are woven together to achieve the singular aim of excellence (Table 180-3). The Baldrige framework inspires leaders to create the culture through which every employee involved in the care of the very ill performs to his or her potential. It sets forth the

TABLE 180-3 Seven Categories of Health Care Criteria for Performance Excellence and Related Key Questions

| CATEGORIES | KEY QUESTIONS |
|--|---|
| 1. Leadership | How does the ICU senior leadership guide the unit through its governance system and organizational performance reviews? How does the ICU leadership ensure sustainability of all key processes at the highest levels of performance, considering innovation? |
| 2. Strategy | How does the ICU establish its strategic objectives and action plans that stretch the ICU, and how are they deployed and measured across the unit? |
| 3. Customers | How does the ICU determine customer/patient requirements, expectations, and preferences, and how does the ICU build relationships with its patients to increase customer/patient engagement in each stage of its relationship? |
| 4. Measurement, analysis, and knowledge management | How does the ICU select, gather, analyze, manage, and improve its measurement system, and how is this knowledge shared, transferred, and communicated throughout the unit? |
| 5. Workforce focus | How does the ICU's work system, staff learning, and staff motivation enable all workforce members to develop and utilize their full potential in alignment with the unit's strategic objectives, goals, and action plans? How do you determine the key factors of engagement for each workforce segment? What are they? |
| 6. Operations | How does the ICU's process management system, including both key processes and support processes, create value for the patient and staff? How do you know? |
| 7. Results | How do the ICU's results compare to competitors and industry benchmarks over time? Are they reflective of the ICU's strategic objectives? |

foundation through which leaders of ICUs can track and achieve results that are comprehensive, balanced, and presented in the context of true world-class performance. It probes the leadership structure to consider how key elements of organizational success are accomplished, how they are systematically deployed throughout the unit, how continuous improvement and the ability to transform is a system

property, and how all the work is aligned with the unit's mission, vision, and values.

ICUs are endowed with extensive human and technologic resources. The first question every ICU leader must ask is: Are we performing at the highest possible level? If the answer is no, then the obligation—not the option—is to achieve it and then sustain it.

KEY POINTS

1. The Baldrige program provides a construct and framework for systematic approaches to achieving excellence and transformation in clinical and organizational performance.
2. Four attributes differentiate high-performing organizations from average ones in terms of work processes: work is done systematically, systematic approaches are fully deployed throughout the organization, ongoing cycles of learning improve the deployed approaches, and all processes are aligned and integrated. These attributes produce results with sustained positive trends that are superior to the competition or industry comparisons.
3. Seven categories of criteria serve as the focus and road map for leaders to achieve role-model performance. These categories are tightly interrelated and provide actionable guidance by identifying existing work process strengths and opportunities for improvement.
4. The Baldrige criteria provide a thoughtful and systematic approach to ensuring attentiveness to patient and family drivers of satisfaction; segmented needs and expectations are integrated throughout the strategic planning process, action plan designs, and overall work processes.
5. The framework provides the ability to empower, motivate, and inspire the ICU and total organizational workforce to achieve its potential and deliver care that meets the needs of patients and families. Such care will be rooted in best-care practices and aligned with the strategic objectives, mission, vision, and values of the unit or organization.

Severity of Illness Indices and Outcome Prediction: Adults

Thomas L. Higgins

And he will manage the cure best who has foreseen what is to happen from the present state of matters.¹

Predicting outcome is a time-honored duty of physicians, dating back at least to the time of Hippocrates.¹ The need for a quantitative approach to outcome prediction, however, is more recent. Although a patient or family members will still want to hear a prognosis, there is increasing pressure to measure and publicly report medical care outcomes. In today's highly competitive healthcare environment, such information may be used to award contracts for care.² Information of variable quality is readily available on the Internet. The U.S. government maintains a Medicare hospital comparison website,³ and comparative information is also available from sites such as www.leapfroggroup.org.⁴ The Physician Quality Reporting System enacts penalties and provides incentives for Medicare providers based on quality.⁵ Local and regional initiatives to assess quality of care also exist. Public reporting of intensive care unit (ICU) performance, in the form of risk-adjusted mortality rates, is now mandated in six European countries⁶ and Veterans Administration (VA) hospitals in the United States.⁷ Estimates are that only 10% to 15% of U.S. ICUs are currently using scoring systems,⁸ but this will increase with the spread of integrated tele-ICU systems and pay-for-performance reimbursement. It has thus become essential for clinicians to understand the science behind these systems⁹ and how risk adjustment models may properly be applied. Risk adjustment systems allow a given outcome (e.g., mortality) to be given to both a patient's intrinsic (disease-related) risk and extrinsic (care-related) causes. Thus, performance (process of care) can be evaluated independent of the presenting condition (baseline risk). A focus on performance assessment, however, may detract from other potential uses for risk stratification, including assisting risk-benefit decisions, prognostication, resource allocation, efficient assessment of new therapy and technology, and modifications to individual patient monitoring and management based on the severity of illness.

Prognostication based on clinical observation is affected by memory of recent events, inaccurate estimation of the relative contribution of multiple factors, false beliefs, and human limitations such as fatigue.¹⁰ An outcome prediction model, on the other hand, will consistently replicate an estimate when considering relevant data. This presupposes that the model has been well developed and includes the most important predictive variables. Over time, we have learned that accepting patients in transfer,¹¹ sociodemographic factors,¹² and the time-point at which an outcome is assessed¹³ can lead to misinterpretation of supposedly objective measures. This chapter will discuss what can (and should) be measured, how benchmarking models are created and assessed, how the most popular models are applied in clinical practice, how this information may be utilized, and the pitfalls and confounders that may imply quality issues when none is actually present.

■ WHAT SHOULD WE MEASURE?

The ancient parable of the blind men and the elephant is relevant to ICU outcome assessment. What is perceived as "quality" depends not only on individual subjective experience but also in integrating multiple perceptions and understanding the limitations of any one observation. Table 181-1 lists over 80 potential metrics categorized into

process measures (what is done) or outcomes (what is achieved) in three bins: quality, efficiency, and patient/family experience. A particular unit may also choose to collect local data on resident and fellow performance, academic pursuits, or additional process measures such as organ donation or autopsy rates. Process measures are important insofar as they provide guidance to interpreting outcomes that are out of range. A high Foley catheter utilization rate will impact the rate of catheter-associated urinary tract infections. With so many metrics to consider, particularly in a multi-ICU hospital, dashboards have become essential. Figure 181-1 displays a "radar" display where every variable has been normalized, such that 1.0 indicates performance at benchmark and the red-shaded areas indicate concern. In this hypothetical example, the Neuro ICU appears to have issues with prolonged hospital length of stay (LOS), possibly related to hospital-acquired conditions. The medical ICU appears to excel at research, publication, and education, while having some issues with patient experience and wait times. Recognizing that some metrics, such as mortality rate and LOS, will be determined primarily by a patient's underlying physiology and health status, rates are normalized using the ratio of observed to expected, creating standardized rates.

A task force of the European Society of Intensive Care Medicine recently defined nine ICU safety and quality indicators based on a modified Delphi procedure. These include designation as an ICU, 24-hour availability of consultants, an adverse event reporting system, routine multidisciplinary rounds, a standardized handover process, rate of catheter-related bloodstream infections, unplanned extubation rates, ICU readmission rate, and reporting and analysis of the standardized mortality rate (SMR).¹⁴ SMR is one of the most frequently utilized outcomes worldwide.⁶ Unfortunately, the lack of standardization on quality metrics makes it difficult to compare quality across (and often within) countries.

Mortality is a commonly chosen ICU and hospital outcome because it is unambiguous and readily available from a variety of data sources. Mortality, while clearly important, does not necessarily reflect quality of care or other important issues such as patient/family satisfaction, return to work, quality of life, or even cost as early death results in a lower cost than prolonged hospitalization.¹⁵ There is poor correlation between hospital rankings based on death and those based on other complications.¹⁶ A retrospective cohort study from 138 U.S. ICUs contributing to Project IMPACT from 2001 to 2008 found that none of the 10 popular quality indicators (e.g., mortality, readmission, LOS, bundle compliance) consistently correlated with the other 9, which questions the wisdom of penalizing institutions for outcomes that are not under their control.¹⁷ There is also little standardization on how mortality should be defined—traditional ICU or hospital rates are subject to discharge bias,¹³ but time-based outcomes (30-day, 1-year mortality rates) require follow-up phone calls, querying nonhospital databases, or other intensive manual processes. Regionalized health information organizations or health information exchanges could make data collection less arduous but are not yet widespread or optimally functional.¹⁸

Other potential outcomes of interest include morbidity, organ failure, complications, ICU or hospital LOS, ICU or hospital

TABLE 181-1 Possible Metrics for Evaluating ICU Performance

| PROCESS MEASURES | QUALITY METRICS | EFFICIENCY | EXPERIENCE | OPTIONAL (LOCAL) |
|---|---------------------|---------------------------|-------------------------|-----------------------|
| Daily wakeup/screen for weaning readiness | ICU SMR | ICU LOS | Patient satisfaction | Trainee performance |
| Glucose control | Hospital SMR | Hospital LOS | Family satisfaction | Publications |
| Lung protective ventilation (Vt/IBW) | 1-year SMR | ICU occupancy (95% CI) | Delirium rate | Funded research |
| Semirecumbent position (HOB at 30) | Sentinel events | Bed turnover rate | Tracheostomy rate | Local research |
| Stress ulcer prophylaxis | CNS events (CVA) | ED to ICU transfer time | % transfer to SNF | Regional transfers in |
| Mobilization of patients | Cardiac events (MI) | ICU to SD/Floor time | Rehabilitation days | Workload (TISS) |
| Communication (Daily Goal transfer) | Respiratory events | Readmission to ICU | 1-year QOL/PICS | Organ donation rate |
| Antibiotic stewardship | Renal events (AKI) | Hospital readmission | Noise levels in ICU | Autopsy rate |
| Medicine reconciliation | GI events (GIB) | Cost/discharge | EOL care and DNR rate | |
| Handwashing | EMR (no cut/paste) | Cost/day | N:P staffing ratio | |
| DVT prophylaxis | DVT and HIT rates | Transfusion rates | MD:patient ratio | |
| Central line utilization and insertion | CLABSI rate | Ratio acute/LTAC days | Provider engagement | |
| Foley utilization and early removal | CAUTI rate | Palliative care referrals | Collaborative practice | |
| Ventilator and NIV utilization rates | VAP rate | Ventilator days | Procedure complications | |
| Assessing sedation RASS / CAMICU | | | | |

AKI, acute kidney injury; CAMICU, confusion assessment method–intensive care unit; CAUTI, catheter-associated urinary tract infection; CLABSI, central line–associated bloodstream infection; CVA, cerebrovascular event; DVT, deep venous thrombosis; ED, emergency department; EMR, electronic medical record; GIB, gastrointestinal bleeding; HIT, heparin-associated thrombocytopenia; LOS, length of stay; MI, myocardial infarction; N:P, nurse to patient; RASS, Richmond agitation-sedation scale; SMR, standardized mortality ratio; NSF, skilled nursing facility; TISS, therapeutic intervention severity score; VAP, ventilator-associated pneumonia.

FIGURE 181-1 ■ Radar display of three hypothetical intensive care units, demonstrating a balanced scorecard approach to outcome assessment. Domains include metrics for quality of care (standardized mortality and hospital-acquired conditions), efficiency (standardized length of stay, readmissions, costs), subjective experience (family satisfaction, provider engagement, quality of life, wait times), and unit-specific measures such as publications, education, and quality of documentation. CVICU, cardiovascular intensive care unit; HAC, hospital-acquired conditions; ICU, intensive care unit; ICUSMR, intensive care unit standardized mortality ratio; LOS, length of stay; MICU, medical intensive care unit; NICU, neuro intensive care unit; SICU, surgical intensive care unit.

readmission, and health-related quality of life after hospital discharge.¹⁹ Events such as myocardial infarction, prolonged ventilation, stroke or other central nervous system complications, renal failure, and serious infection can be difficult to collect accurately. With electronic medical records and good coding, comorbidities may be identified by ICD-9 and international classification of disease (ICD)-10 codes,²⁰ but administrative records may not reflect all relevant events.²¹ ICU LOS is difficult to use as a proxy for quality of care because the frequency of distribution is usually skewed and the mean LOS is always higher than the median LOS owing to long-stay outliers.²² In addition, early death shortens the LOS, resulting in a nonlinear relationship between the two outcomes. It is difficult to develop accurate models for ICU LOS at admission²³; discrimination is usually inferior to that of mortality models based on the same database. A variety of regression methods have been applied to LOS prediction, with somewhat disappointing results.²⁴ More success has been achieved by combining variables from ICU day 1 and day 5; variables with the most impact include mechanical ventilation, the $\text{PaO}_2/\text{FiO}_2$ ratio, physiologic components, and day 5 sedation.²⁵

Patients readmitted to ICUs have increased hospital mortality and LOS. However, readmission rates are difficult to interpret without careful case-mix adjustment.²⁶ Readmission rates are affected by triage decisions when ICU beds are constrained, but one study suggests that readmissions are only slightly higher with bed constraints, and, in any case, do not appear to affect short-term patient outcomes.²⁷ In a retrospective study of 263,082 first-admission patients in 105 U.S. hospitals, the median unit readmission rate was 5.9% (interquartile range, IQR, 5.1% to 7.0%). Hospitals with high readmission rates, however, did not have higher standardized mortality rates or LOS after case-mix adjustment.²⁸

Patient satisfaction is an outcome highly valued by purchasers of health care, but it is subjective and requires substantial effort to quantify successfully.²⁹ Evaluation of ICU performance requires a combination of indicators, but risk adjustment has mostly been developed for short-term mortality outcomes, with only a few studies risk-adjusting for other indicators.

DATABASES AND DEFINITIONS

The quality of a risk stratification system largely depends on the database from which it was developed. Retrospective studies using existing data are quicker and less expensive but may be compromised by missing data, imprecise definitions, interobserver variability,³⁰ and changes in medical practice over time. Data derived from discharge summaries or insurance claims do not always capture the presence of comorbid disease³¹ if the number of reportable events is truncated, and this coding bias is most apparent in severely ill patients.²² Coding errors and algorithms that optimize diagnosis-related group reimbursement also reduce the validity of claims-derived data. A variety of methods can assess the quality of the database, such as reabstraction of a sample of charts by personnel blinded to the initial results. Kappa analysis is a method for quantifying the rate of discrepancies between measurements (values) of the same variable in different databases (i.e., original and reabstracted). A kappa value of 0 represents random agreement and of +1.0 represents perfect agreement, but this statistic must be interpreted in light of the prevalence of the factor being abstracted.³²

MODEL DEVELOPMENT

Once data integrity is ensured, there are several possible approaches that relate outcome to the presenting condition.⁹ The empiric approach is to use a large database and subject the data to a series of statistical manipulations (Box 181-1). Typically, death, one or more specific morbidities, and resource consumption (LOS) are chosen as outcomes (dependent variables). Factors (independent variables) thought to affect outcome are then evaluated against a specific outcome using univariate tests to establish the magnitude and significance of any relationship.⁹

BOX 181-1

Steps in Developing a Severity-of-Illness Model

Precisely define outcome(s) of interest.
Identify and define candidate predictor variables (data analysis, expert opinion).
Collect data, and ensure its accuracy (reabstraction, kappa analysis).
Examine continuous variables, and transform or dichotomize as necessary.
Perform univariate analysis (chi-square, Fisher's exact, Student's t-test) against outcome(s).
Perform multivariate analysis (logistic regression, neural nets, Bayesian, others).
Examine and adjust for interactions among variables.
Develop a score or equation that relates independent variables to outcome.
Test calibration of model (goodness of fit, typically Hosmer-Lemeshow method).
Test discrimination of model (ROC area C-statistic, sensitivity, and specificity).
Validate model with independent data, split sample, or jackknife techniques.
Obtain external validation in new settings, and customize as needed.
Publish in peer-reviewed journal.

WHAT INDEPENDENT VARIABLES AFFECT OUTCOME?

ICU-specific systems typically adjust for patient physiology, age, and chronic health condition; they may also assess admitting diagnosis, location before ICU admission or transfer status, cardiopulmonary resuscitation before admission, surgical status, and mechanical ventilation use. An ideal approach would use only variables that characterize a patient's initial condition, can be statistically and medically related to outcome, are easy to collect, and are independent of treatment decisions. There is also benefit to serial assessment of the condition as the influence of independent variables may vary throughout the hospitalization.³³ The Glasgow Coma Scale³⁴ (GCS) is frequently used as a component of ICU severity scores but can be difficult to calculate correctly in sedated patients. The Full Outline of UnResponsiveness score,³⁵ which includes information on brainstem reflexes and respiration, is emerging as an alternative with slightly better accuracy than GCS as a mortality predictor.

Measured variables such as "cardiac index" or "hematocrit" are preferred over "use of inotropes" or "transfusion given" because the criteria for intervention may vary by provider or hospital. Widely used models rely on common measured physiologic variables (heart rate, blood pressure, and neurologic status) and laboratory values (serum creatinine level and white blood cell count). Models may consider age and chronic health status and include interaction terms when variables are not independent. Items chosen for inclusion in a scoring system should be readily available and relevant to involved clinicians. Specialized scoring systems become necessary for specific patient populations (pediatric, burn, trauma, cardiac surgery) whose underlying physiology or treatment course differs from that of the general adult ICU population. For example, left ventricular ejection fraction and reoperative status are important predictors of outcome in the cardiac surgical population but are neither routinely measured nor directly relevant to other population groups.³⁶

If the independent variable is dichotomous (yes/no, male/female), a two-by-two table can be constructed to examine the odds ratio and a chi-square test performed to assess significance (Table 181-2). If multiple variables are being considered, the level of significance is generally set smaller than $P = 0.05$, using a multiple comparison correction.³⁷

If the independent variable under consideration is continuous (e.g., age), a Student's t-test is an appropriate choice for statistical comparison. With continuous variables, consideration must be given to whether the relationship of the variable to outcome is linear, exponential, or segmented across its range. Figure 181-2 shows the relationship of ICU admission serum bicarbonate to mortality outcome in cardiac surgical patients³⁸; data points have been averaged with adjacent values to produce a smoothed graph.³⁹ Serum bicarbonate values higher than

TABLE 181-2

Two-by-Two Contingency Table Examining Relationship of MOF After Open Heart Surgery (Outcome) to a History of CHF (Predictor) in 3830 Patients*

| PREDICTOR VARIABLE: HISTORY OF CHF | OUTCOME VARIABLE: MOF | |
|---------------------------------------|--------------------------|------|
| | YES | NO |
| Yes | 121 | 846 |
| No | 166 | 2697 |

*The odds ratio is defined by cross-multiplication $(121 \times 2697) \div (846 \times 166)$. The odds ratio of 2.3 indicates patients with CHF are 2.3 times as likely to develop postoperative organ system failure as those without prior CHF. This univariate relationship can then be tested by chi-square for statistical significance.

CHF, congestive heart failure; MOF, multiple organ failure.

Data from Higgins TL, Estafanous FG, Loop FD, et al. ICU admission score for predicting morbidity and mortality risk after coronary artery bypass grafting. *Ann Thorac Surg* 1997;64:1050–108.

FIGURE 181-2 ■ A locally weighted smoothing scatterplot (LOWESS) analysis of the relationship between ICU admission bicarbonate level (x-axis) and mortality (y-axis). Individual patient data are grouped and averaged with surrounding data to produce a smooth plot. In this instance, the mortality rate appears to be stable with admission serum bicarbonate levels of 22 mmol/L and above but rises rapidly with lower values. Admission bicarbonate level of less than 21 mmol/L was given prognostic weight in the model that used these data. (Data from Higgins TL, Estafanous FG, Loop FD, et al. ICU admission score for predicting morbidity and mortality risk after coronary artery bypass grafting. *Ann Thorac Surg* 1997;64:1050–1058.)

22 mmol/L at ICU admission imply a relatively constant risk. Below this value, the risk of death rises sharply. Analysis of this locally weighted smoothing scatterplot graph suggests two ways for dealing with the impact of serum bicarbonate on mortality. One would be to make admission bicarbonate a dichotomous variable (i.e., >22 mmol/L or <22 mmol/L). The other would be to transform the data via a logarithmic equation to make the relationship more linear. Cubic splines analysis⁴⁰ can be helpful when the relationship between independent and dependent variables is not linear or cannot be described by a simple transformation.

Univariate analysis assesses the forecasting ability of variables without regard to possible correlations or interactions between them. Linear discriminant and logistic regression techniques can evaluate

TABLE 181-3

Variables in the MPM₀ III Logistic Regression Model

| VARIABLE | ODDS RATIOS (95% CONFIDENCE INTERVALS) | COEFFICIENTS (ROBUST STANDARD ERRORS) |

and correct for overlapping influences on outcome. For example, both a history of heart failure and depressed left ventricular ejection fraction predict poor outcome in patients presenting for cardiac surgery.⁴¹ As might be expected, there is considerable overlap between the population with systolic heart failure and those with low ejection fraction. The multivariate analysis in this specific instance eliminates history of heart failure as a variable and retains only measured ejection fraction in the final equation to avoid double-counting of this general risk.

Because linear discriminant techniques require certain assumptions about data, logistic techniques are more commonly utilized.⁹ Multiple logistic regression produces an equation with a constant, a β coefficient and standard error, and an odds ratio that represents each term's effect on outcome. Table 181-3 displays the results of the logistic regression used in the Mortality Probability Model III ICU admission model (MPM₀ III).⁴² There are 17 variable terms, and a constant term, each with a β value that, when multiplied by the presence or absence

of a factor, becomes part of the calculation of mortality probability using a logistic regression equation. The odds ratios reflect the relative risk of mortality if a factor is present. The challenge in building a model is to include sufficient terms to deliver reliable prediction while keeping the model from being cumbersome to use or too closely fitted to its unique development population. Generally accepted practice is to limit the number of terms in the logistic regression model to 10% of the number of patients having the outcome of interest to avoid “overfitting” the model to the developmental dataset. It is important to identify interaction among variables that may be additive, subtractive (canceling), or synergistic and thus require additional terms in the final model. In the earlier example, seven interaction items were added to reflect important observations in elderly patients,⁴³ where the very old without significant comorbidity frequently have better outcomes than unhealthy younger individuals.

The patient’s diagnosis is an important determinant of outcome,⁴⁴ but conflicting philosophies exist on how disease status should be addressed by a severity adjustment model. One approach is to define principal diagnostic categories and add a weighted term to the logistic regression equation for each illness.⁴⁵ This acknowledges the different impact of physiologic derangement by diagnosis. For example, patients with diabetic ketoacidosis have markedly altered physiology but a low expected mortality; a patient with an expanding abdominal aneurysm, conversely, may show little physiologic abnormality and yet be at high risk for death. Too many diagnostic categories, however, may result in too few patients in each category to allow statistical analysis for a typical ICU, and such systems are difficult to use without sophisticated (and often proprietary) software.

The other approach is to ignore disease status and assume that factors such as age, chronic illness, and altered physiology will suffice to explain outcome in large groups of patients. This method reduces manual data collection and avoids issues with inaccurate labeling of illness in patients with multiple problems and the need for lengthy lists of coefficients but could result in a model that is less accurate⁴⁶ and somewhat dependent on having an “average” case mix.⁴⁷ Regardless of the specific approach, age and comorbidities (metastatic or hematologic cancer, immunosuppression, and cirrhosis) are given weight in nearly all ICU models to help account for the patient’s physiologic reserve or ability to recover from acute illness. Yet, many influential variables (e.g., frailty⁴⁸ in elders, mental illness,⁴⁹ paraplegia) increase the risk of poor outcome but are seldom incorporated into models. For example, acutely intoxicated patients tend to have low in-hospital mortality, but striking rates of long-term mortality, particularly when street drugs are the intoxicating agent.⁵⁰ Do-not-resuscitate orders are a strong confounder in mortality evaluations⁵¹ but have only been included as a scoring variable in more recent models.⁴²

**VALIDATION AND TESTING
MODEL PERFORMANCE**

Models may be validated on an independent dataset or by using the development set with methods such as jackknife or bootstrap validation.⁵² Two criteria are essential in assessing model performance: calibration and discrimination. *Calibration* refers to how well the model tracks outcomes across its relevant range. A model may be very good at predicting good outcomes in healthy patients and poor outcomes in very sick patients yet unable to distinguish outcomes for patients in the middle range. The Hosmer-Lemeshow goodness-of-fit test⁵³ assesses calibration by stratifying the data into categories (usually deciles) of risk. The number of patients with an observed outcome is compared with the number of predicted outcomes at each risk level. If the observed and expected outcomes are very close at each level across the range of the model, the sum of chi-squares will be low, indicating good calibration. The *P* value for the Hosmer-Lemeshow goodness-of-fit *increases* with better calibration and should be nonsignificant (i.e., >0.05). Special precautions apply when using the Hosmer-Lemeshow tests with very large databases,⁵⁴ where massive numbers can produce significance without true importance.

TABLE 181-4 Classification Table

| PREDICTED OUTCOME | ACTUAL OUTCOME | |
|-------------------|----------------|----------|
| | DIED | SURVIVED |
| Died | a | c |
| Survived | b | d |

True-positive ratio = $a/(a + b)$ (sensitivity)
False-positive ratio = $c/(c + d)$
True-negative ratio = $d/(c + d)$ (specificity)
False-negative ratio = $b/(a + b)$
Accuracy (total correct prediction) = $(a + d)/a + b + c + d$
Adapted from Ruttiman UE. Severity of illness indices: development and evaluation. In: Shoemaker WC, ed. Textbook of critical care medicine. 2nd ed. Philadelphia: Saunders; 1989.

The second measurement of model performance is *discrimination*, or how well the model predicts the correct outcome. A classification table (Table 181-4) displays four possible outcomes that define sensitivity and specificity of a model with a binary (died/survived) prediction and outcome. Sensitivity (the true-positive rate) and specificity (the true-negative rate, or 1—the false-positive rate) are measures of discrimination but will vary according to the decision point chosen to distinguish among outcomes when a model produces a continuous range of possibilities. The sensitivity and specificity of a model when using 50% as the decision point will differ from that using 95% as the decision point. The classification table can be recalculated for a range of outcomes by choosing various decision points: for example, 10%, 25%, 50%, 75%, and 95% mortality risk. At each decision point, the true-positive rate (proportion of observed deaths predicted correctly), the false-negative rate (proportion of survivors incorrectly predicted to die), and overall correct classification rate can be presented. The C-statistic, or area under a receiver-operating characteristic (ROC) curve, is a convenient way to summarize sensitivity and specificity at all possible decision points. A graph of the true-positive proportion (sensitivity) against the false-positive proportion (1—specificity) across the range of the model produces the ROC curve (Fig. 181-3). A model with equal probability of producing the correct or incorrect result (e.g., flipping a coin) will produce a straight line at a 45-degree angle that encompasses half of the area (0.5) under the curve. Models with better discrimination will incorporate increasingly more area under the curve to a theoretical maximum of 1.0. An area under the ROC curve (auROC) higher than 0.70 is acceptable, with higher than 0.80 considered excellent, and higher than 0.90 outstanding.⁸ Most ICU models have ROC areas of 0.8 to 0.9 in their development set, although the ROC area usually decreases when models are applied prospectively to new datasets. The ROC analysis is valid only if the model has first been shown to be well calibrated.

A model may discriminate and calibrate well on its development dataset yet fail when applied to a new population.⁵⁵ Discrepancies in performance can also relate to differences in surveillance strategies and definitions⁵⁵ and can occur when a population is skewed by an unusual number of patients having certain risk factors, as could be seen in a specialized ICU.⁴⁷ Large numbers of low-risk ICU admissions will result in poor predictive accuracy for the entire ICU population.⁵⁶ The use of sampling techniques (i.e., choosing to collect data randomly on 50% of patients rather than all patients) also appears to bias results.⁵⁷ Models deteriorate over time,⁵⁸ owing to changes in populations and medical practice. These explanations should be considered before concluding that quality of care is different between the original and later applications of a model.

STANDARDIZED MORTALITY RATIO

Application of a severity of illness scoring system involves comparison of observed outcomes with those predicted by the model. The *standardized mortality ratio* (SMR) is defined as observed divided by

FIGURE 181-3 ■ Relative operating characteristic (ROC) curves. A coin toss gives an ROC of 0.5. In models that discriminate outcome, an increasing area under the curve, also called the *C-statistic*, is enclosed. (From Swets JA. Measuring the accuracy of diagnostic systems. *Science* 1988;240:1285–1294.)

expected mortality and is generally expressed as a mean value $\pm 95\%$ confidence intervals (CIs), which will depend on the number of patients in the sample. SMR values of 1.0 (\pm the CI) indicate that the mortality rate, adjusted for presenting illness, is at the expected level. Standardized mortality ratio values significantly lower than 1.0 indicate performance better than expected. Small differences in scores, as could be caused by consistent errors in scoring elements, timing of data collection, or sampling rate, cause important changes in the SMR.^{38,59} Different models applied to the same dataset may produce discordant results, with the same hospital being identified as performing better than expected by one model and worse than expected by another.⁴⁶

MODELS BASED ON PHYSIOLOGIC DERANGEMENT

Three widely utilized general-purpose ICU outcome systems are based on changes in patient physiology: the Acute Physiology and Chronic Health Evaluation (APACHE II,⁶⁰ APACHE III,⁶¹ APACHE IV⁴⁴), the Mortality Probability Models (MPM₀-II,⁶² MPM₂₄-II,³³ MPM₀-III),⁴² and the Simplified Acute Physiology Score (SAPS II,⁶³ SAPS III^{64,65}). MPM₀-II and SAPS II were developed from the same dataset and initially shared variables. All models have been regularly updated and are in at least their third generation. Although variables and weighting differ, all are based on the premise that as critical illness increases, patients will exhibit greater deviation from physiologic normal for a variety of common parameters such as heart rate, blood pressure, neurologic status, and laboratory values. Risk is also assigned for advanced age and chronic illness. Variables from these models have also been incorporated into the U.S. Veterans Administration hospital system model⁶⁶ (based on APACHE) and the California Outcomes Study⁶⁷ (similar to MPM₀-II and -III), as well as to models customized for international populations.

Acute Physiology and Chronic Health Evaluation

APACHE II was developed from data on 5815 adult medical and surgical ICU patients at 13 hospitals between 1979 and 1982; patients undergoing coronary artery bypass grafting, coronary care, or burn

treatment were not part of the initial analysis. Severity of illness was assessed with 12 routine physiologic measurements plus the patient's age and previous health status.⁶¹ Scoring was based on the most abnormal measurements during the first 24 hours in the ICU, with a maximum score of 71 points. The physiology score was then combined with coefficients to adjust the score for 29 nonoperative and 16 post-operative diagnostic categories, producing a mortality estimate.

APACHE II does not control for admission source or pre-ICU management, which could restore a patient's altered physiology and lead to a lower score and thus underestimate a patient's true risk.⁶⁸ Mortality estimates are most accurate for patients admitted directly from the emergency department and less so for inter- and intra-hospital transfers. Failure to consider the location prior to ICU admission could thus lead to erroneous conclusions about the quality of medical care.⁶⁹ Although the developers now consider APACHE II to have significant limitations based on its age, it is still in widespread use.

APACHE III, published in 1991, addressed limitations of APACHE II, including the impact of treatment time and location before ICU admission.⁶² The number of separate disease categories was increased from 45 to 78. APACHE III was developed on a representative database of 17,440 patients at 40 hospitals, including 14 tertiary facilities that volunteered for the study and 26 randomly chosen hospitals in the United States. APACHE III went through several partial updates between 1991 and 2003.⁴⁵ Compared with APACHE II, the ranges of physiologic "normal" are narrower; deviations from normal are asymmetrically weighted to be more clinically relevant. Interactions between variables were considered, and five new variables (blood urea nitrogen, urine output, serum albumin, bilirubin, and glucose) were added, while APACHE II variables serum potassium and bicarbonate were dropped. Information was also collected on 34 chronic health conditions, of which seven (AIDS, hepatic failure, lymphoma, solid tumor with metastasis, leukemia/multiple myeloma, immunocompromised state, and cirrhosis) were significant in predicting outcome. Customized models were developed for patient populations (e.g., cardiac surgery)⁷⁰ excluded from APACHE II. Overall correct classification for APACHE III was much improved over the prior model, and for the first time sequential scoring was introduced to update the daily risk estimate. APACHE III scores were also correlated with predictions for ICU LOS, need for interventions, and nursing workload.

APACHE IV was published in 2006⁴⁴ with refinements to address the impact of sedation on GCS, expand the number of diagnostic groups, and to add or rescale predictive variables (Table 181-5). APACHE IV, based on a sample of 110,558 patients in the United States, has excellent discrimination (ROC area = 0.88) and impressive calibration (Hosmer-Lemeshow C statistic 16.8, $P = 0.08$). Outcome assessment using the revised model differed substantially from prior versions. A hospital using APACHE III software in 2006, for example, (calibrated to 1988-89 results) might have congratulated themselves on a superb SMR of 0.799, whereas using APACHE IV would have revealed their SMR to be not different from average at 0.997. APACHE IV relies on physiologic abnormalities to account for 66% of the model's explanatory power. ICU admission diagnosis (using 116 categories) accounts for about 17%, with the remainder accounted for by age, chronic illness, location prior to admission, and interaction terms. There are limitations to the use of APACHE IV. First, the increased complexity of the model makes it impossible to use without dedicated software. The data entry burden, however, can be mitigated by porting data into APACHE from a hospital's clinical information system. Second, APACHE IV was developed and validated in ICUs in the United States, and international differences in ICU resources, triage policies, models of care, and bed availability impact benchmarking performance in a new environment.⁷¹ The authors also stress that "prediction for an individual contains variance" and that "a prediction is only an approximate indicator of an individual's probability of mortality."⁴⁴ As an example, they mention that the 95% CIs around a predicted mortality of 5% would typically be 3.9% to 6.5% and that the absolute ranges of CIs widen as the predicted rate increases. APACHE

IV has been recalibrated to APACHE IVa, and APACHE V is currently under development.

Mortality Probability Models

The original Mortality Probability Model (MPM) was developed on 755 patients at a single hospital using multiple logistic regression to assign weights to variables predicting hospital mortality.⁷² The MPM-II models were developed on an international sample of 12,610 patients and then validated on a subsequent sample of 6514.³³ A subscript (0, 24, 48, 72) designates time of the evaluation in approximate hours post admission. MPM-II, as with APACHE II, excluded pediatric, burn, coronary, and cardiac surgical patients and estimated hospital mortality risk based partly on physiologic derangement, using a smaller number of variables. However, MPM puts more weight on chronic illness, comorbidities, and age and less on acute physiologic derangement compared with APACHE. MPM models can use data obtained at ICU admission (MPM₀) and also at the end of the first 24-hour period (MPM₂₄), the latter covering a time interval more comparable to APACHE. While APACHE generates a score and then, with additional information, converts that score into a probability estimate of survival, MPM directly calculates a probability of survival from the available data. Because this involves a logistic regression equation, it is difficult to accomplish at bedside without a computer or programmable calculator. The MPM₂₄ variables account for differences in patients who remain in the ICU for 24 hours or longer versus those

who die early or recover rapidly. This line of reasoning has been further extended to create 48- and 72-hour models,⁷³ although these have not yet been updated from MPM-II to MPM-III. Additional variables in MPM₂₄, MPM₄₈, and MPM₇₂, but not MPM₀ are prothrombin time, urine output, creatinine, arterial oxygenation, continuing coma or deep stupor, confirmed infection, mechanical ventilation, or intravenous vasoactive drug therapy. Probability of death increases at 48 and 72 hours even if the MPM variables and coefficients are unchanged, implying that mortality risk is increasing in patients whose clinical profile remains unchanged over time.⁷⁴ The most important difference between MPM and APACHE is that the MPM₀ produces a probability estimate that is available at ICU presentation and is independent of ICU treatment. MPM also does not require specifying a diagnosis, which can be an advantage in complex ICU patients but may also make it more susceptible to error with changes in case mix⁴⁷ and generates, on average, a lower area under the ROC curve.

MPM₀-II became the mortality benchmarking component for the Society of Critical Care Medicine's (SCCM) Project IMPACT database launched in 1996. By 2002, it was apparent that mortality predictions based on mid-1980s results were outdated, and average SMRs in Project IMPACT hospitals had drifted to 0.85.⁷⁴ MPM₀-III was developed from a population of 124,855 patients in 135 ICUs at 98 Project IMPACT hospitals. Hospital mortality in this population was 13.8% versus 20.8% in the MPM₀-II cohort.⁴² All of the 15 variables from MPM₀ II remained associated with mortality, but the relative impact had changed. For example, gastrointestinal bleeding was no longer a serious risk factor, presumably because of advances in resuscitation, endoscopic procedures, treatment of *H. pylori*, and availability of proton pump inhibitors since the original study. Additionally, two new variables were added: "full code" resuscitation status at ICU admission and "zero factor" or absence of all MPM₀-II risk factors except age. Seven age interaction terms were added to reflect the declining marginal contribution of acute and chronic medical conditions to mortality risk in the elderly.⁴³ MPM₀-III calibrated well (Hosmer-Lemeshow goodness-of-fit 11.62; *P* = 0.31) with an area under the ROC curve of 0.823, similar to that of MPM₀-II. While the ROC area is lower than with APACHE, MPM users do not need to specify a diagnosis, which may be difficult in a complex patient with multiple problems. The simplicity of data collection and ability to generate a prognosis soon after arrival (rather than at 24 hours) are advantages. Limitations of the MPM₀-III include lower discrimination and use of a self-selected population of Project IMPACT participants in North America. While in theory, extreme case-mix differences might affect MPM performance, in practice, SMRs obtained using MPM₀-III versus specially constructed subgroup models were nearly identical in the 135 ICUs studied, suggesting specialized subgroup models are not usually necessary.⁷⁵ MPM₀-III has been prospectively validated on an additional 55,459 patients at 103 adult ICUs in North America and calibrates well with more contemporary Project IMPACT hospitals (78 units participating in both studies plus 25 new participants).⁷⁶ The Project IMPACT database was also used to update the resource utilization "Rapoport Teres" graph that plots severity-adjusted mortality versus severity-adjusted LOS⁷⁷ (Fig. 181-4).

The California Intensive Care Outcomes Projects (CALICO) was developed to produce public reports comparing outcomes for patients treated in California ICUs as part of the larger California Hospital Outcomes Project mandated by the State of California.⁶⁸ After evaluating risk models available in the early 2000s, the California Healthcare Foundation and the National Quality Forum endorsed a modified and recalibrated version of the MPM₀-II model termed "ICU Outcomes Model" or ICOM_{mort},⁷⁸ which has an auROC of 0.84 in prospective validation. The model includes 28 additional interaction terms and differs in patient exclusions from MPM-II and MPM-III. An additional model (ICOM_{LOS}) considers LOS. The CALICO project yielded several important findings, most notably that substantial (2-fold) variation exists in mortality rates among hospitals, even after risk adjustment.⁶⁸ Beginning in 2007, California required every ICU in the state to report severity-adjusted mortality rates. A recent study of 936,063 patients

FIGURE 181-4 ■ Project IMPACT consolidates the display of MPM severity-adjusted mortality data (x-axis) with standardized resource use (weighted hospital days, y-axis). Hospitals within the 1 and 2 standard deviation boxes (most observations) are performing as expected. One hospital in the upper-right corner has superior performance in both dimensions. Four hospitals have longer than expected length of stay (negative numbers on standardized resource use), while being within range for mortality. Three hospitals have worse than expected adjusted mortality, while two have better than expected mortality; all are still within expected resource utilization. (From Nathanson BH, Higgins TL, Teres D, et al. A revised method to assess ICU clinical performance and resource utilization. *Crit Care Med* 2007;35:1853–1862.)

comparing the California experience to that of Arizona, Nevada, and Texas (which did not have public reporting requirements) concluded that while outcomes in California had improved, mortality rates also decreased in the control states.⁷⁹

Simplified Acute Physiology Score

SAPS II⁶⁴ was developed on 13,152 patients at 137 adult medical or surgical ICUs in Europe and North America, sharing the MPM-II dataset. Like MPM and APACHE-II, SAPS excluded burn patients, patients younger than 18 years, coronary care patients, and cardiac surgery patients. The outcome measure for SAPS II was vital status at hospital discharge. Seventeen variables were used in the SAPS II model: 12 physiologic variables, age, type of admission, and the presence of AIDS, metastatic cancer, or hematologic malignancy.

Not surprisingly, the SAPS II model also drifted out of calibration over time.⁶⁵ SAPS III, a multicenter, multinational study, collected data on 19,577 patients from 307 ICUs during the fall of 2002. SAPS II, when applied to this cohort, underestimated hospital mortality, and, while it discriminated well (ROC area, 0.83), calibration was poor, and model performance differed by geographic region. The final SAPS III model (Box 181-2), created based on 16,784 patients using logistic regression methods, contains 20 variables and has good discrimination (ROC area 0.848) and calibration (Hosmer-Lemeshow $C = 14.29$; $P = 0.16$).⁶⁶ Customized models were generated for seven worldwide regions to address geographic variation in population outcomes.

Intensive Care National Audit and Research Center Model

As noted earlier, risk adjustment models require validation and recalibration if they are to be applied in a new geographic setting.^{55,80} The Intensive Care National Audit and Research Center (ICNARC)

BOX 181-2

Variables Used in Simplified Acute Physiology Score Iii

Age (in years)
Comorbidities: cancer, cancer therapy (scored separately), chronic heart failure (NYHA IV), hematologic cancer, cirrhosis, AIDS
Length of stay before intensive care unit (ICU) admission, days
Intrahospital location before ICU admission
Use of major therapeutic options before ICU admission (e.g., vasopressors)
ICU admission: planned or unplanned
Reason for ICU admission
Surgical status at ICU admission: emergency, elective, or none
Anatomic site of surgery
Acute infection at ICU admission
Lowest estimated Glasgow Coma Scale score (points)
Total bilirubin (highest)
Body temperature (highest)
Creatinine (highest)
Heart rate (highest)
Leukocytes (highest)
Hydrogen ion concentration (lowest pH)
Platelet count (lowest)
Systolic blood pressure (lowest)
Oxygenation (P/F ratio)

BOX 181-3

Elements in ICNARC Score

Highest heart rate
Lowest systolic BP
Highest temperature
Lowest respiratory rate
Mechanical ventilation (Yes/No)
Lowest Pao₂/associated FiO₂ (P/F ratio)
Lowest pH
Highest serum urea
Highest serum creatinine
Highest serum sodium
Urine output (24 hours)
Lowest WBC
Paralyzed/sedated (Yes/No)
Lowest Glasgow Coma Scale score
Age, years
Source of admission
Diagnostic category
CPR (Yes/No)

collected data on 216,626 critical care admissions in 163 adult general critical care units in England, Wales, and Northern Ireland from December 1996 to August 2003.⁸¹ Logistic regression techniques were used to create the ICNARC model (Box 181-3), which includes 12 physiologic variables, age, source of admission, diagnostic category, and CPR status. This model has an ROC area of 0.863 and a Hosmer-Lemeshow C statistic of 64.2. This study also evaluated performance of APACHE II, APACHE III, SAPS II, and MPM-II on the same population. The ICNARC outperformed all other models in terms of discrimination (ROC area), but SAPS II had better calibration, while MPM-II had the best accuracy of average prediction, although these differences were all relatively minor. ICNARC, having no exclusions, may be applied to all critical care admissions regardless of diagnosis, and it calibrates well in the United Kingdom. ICNARC has recently been externally validated in 23,269 patients in 24 Scottish critical care units, with good discrimination (0.848) and calibration.⁸²

Veterans Affairs Intensive Care Unit Risk Adjustment Model

Arguably, the Veterans Affairs (VA) population in the United States could represent a specialized population, owing to being predominantly male (>97%). In 1996-97, the VA developed a customized, automated ICU risk adjustment tool⁶⁷ based on APACHE variables; this model has been validated, updated, and recalibrated.⁸³ Risk predictors include age, mutually exclusive ICD-9 diagnosis/procedure groups, comorbid disease groups, admission source, and 11 laboratory values measured during the 24 hours surrounding ICU admission. Revisions to the model refit the predictor coefficients and expanded the number of diagnostic categories from 38 to 84. The model has an impressive ROC area (0.874-0.877) in two data cohorts and calibrates well by Hosmer-Lemeshow statistics. SMRs derived from the VA ICU model correlate well ($r^2 = 0.74$) with those of the National Surgical Quality Improvement Performance (NSQIP) tool developed for surgical post-operative assessment. The VA model, however, has not yet been tested internationally or outside of the VA population.

Specialized Models

MPM, SAPS, and early versions of APACHE excluded patients younger than age 18, burn patients, and coronary care and cardiac surgical patients. Murphy-Filkins et al.⁴⁷ reported that performance of severity of illness models deteriorates when critical population values are reached for individual scoring variables, as might be seen in a highly specialized ICU. For example, 20% of the patients in the MPM-II database were aged 75 or older. When this percentage of elderly patients was experimentally increased to 42%, the model became unstable. Similar changes were seen if the proportion of patients with cardiac dysrhythmias, cerebrovascular disease, intracranial mass effects, coma, cardiopulmonary resuscitation before ICU admission, emergency admission, or gastrointestinal bleeding differed substantially from baseline values. Thus, severity of illness scoring systems should be used with caution when units become highly specialized to care for subsets of patients.

To address this issue, specific models have been developed for pediatric,⁸⁴ trauma,⁸⁵ and cardiac surgical populations.^{41,86-88} ICU admission physiologic values in the cardiopulmonary bypass population are determined by routine hypothermia, hemodilution, and deliberate control of hemodynamics by the operating room team. Important variables for predicting outcome after cardiac surgery are ventricular function, coronary anatomy, and heart valve pathology and reoperation status.³⁶ The Cooperative CABG Database Project, analyzing 172,000 patients, identified seven core variables (urgency of operation, age, prior heart surgery, gender, ejection fraction, percent stenosis of the left main coronary artery, and number of major coronary arteries with >70% stenosis) to be predictive of mortality.⁸⁹ The independent variables predicting morbidity do not perfectly overlap those predicting mortality or LOS, suggesting that different scores may be required to best predict various outcomes. Currently, the two most widely used preoperative cardiac surgical models are the Society for Thoracic Surgeons model⁹⁰ in the United States and the EuroSCORE-II⁹¹ in Europe; both have been updated from their original iterations.

The preoperative cardiac surgical models are useful for evaluating the results of an entire hospitalization but do not specifically address the ICU component of care. Operating room events can neutralize or amplify preoperative risk, depending on such events as reopening the chest, hemodynamic management in an emergency patient, and the degree of myocardial protection. In 5000 patients undergoing CABG, eight risk factors available at ICU admission appeared to predict hospital mortality, and an additional five factors also predict morbidity.³⁸ APACHE has also been successfully modified for use in cardiac surgical patients.⁷¹

Patients receiving prolonged mechanical ventilation (MV) are resource-intensive, and, although their mortality can be accurately

estimated, they have a disproportionate effect on ICU and hospital LOS which is magnified with high hospital MV volume.⁹² The ProVent model, measured on day 21 of MV, predicts overall 1-year mortality (48%) with acceptable discrimination and calibration⁹³ by assigning points for four categorical variables: age, platelet count, vasopressors, and hemodialysis.

SEQUENTIAL ORGAN FAILURE ASSESSMENT (SOFA) SCORE

The sequential organ failure assessment (SOFA) score was developed to quantify organ dysfunction of the respiratory, cardiovascular, hepatic, coagulation, renal, and neurologic systems. One to four points are assigned based on the degree of physiologic derangement; high scores imply poor outcome. A maximum SOFA higher than 15 is associated with more than 90% mortality.⁹⁴ SOFA is intended to be used sequentially, in part to address the issue that a first-day severity score has limited ability in predicting outcome when patients have a longer ICU experience with attendant events or complications. Although developed to assess organ failure rather than prognosis, SOFA (and similar scores, such as the Logistic Organ Dysfunction System [LODS]⁹⁵ and the Multiple Organ Dysfunction Score [MODS])⁹⁶ correlates with mortality. The change in score during the first 96 hours can help with prognosis: regardless of the initial score, an increasing score is associated with more than 50% mortality.⁹⁷

Most risk-adjustment models provide initial estimates for both ICU and hospital mortality, with the potential for updating predictions during the ICU stay. While subjective, the Sabadell score allows ICU clinicians to categorize patients at ICU discharge into good prognosis (0 points), poor long-term prognosis (>6 months) with unlimited ICU readmission (1 point), poor short-term prognosis (<6 months) with debatable ICU readmission (2 points), and death expected during hospitalization (3 points). Age and the Sabadell score correlate with ward mortality following ICU discharge with good calibration (AuROC, 0.88) and discrimination.⁹⁸ Patients with high predicted ward mortality would likely benefit from palliative care consultation. Conversely, less than 2% of patients with good prognosis die on the ward after ICU discharge.

ADMINISTRATIVE MODELS

Initial versions of the most popular models were developed by research teams using data largely collected manually using trained abstractors.⁴⁵ There has been interest in automating this process,⁹⁹ and with the widespread availability of electronic health records, real-time calculations have become routine. Although extracting relevant clinical variables can still be an informatics challenge, successful models based on administrative data have been developed for predicting in-hospital mortality for community-acquired pneumonia¹⁰⁰ and sepsis.¹⁰¹ With automated data collection, these models can extend beyond just ICU admissions to encompass all hospitalized patients. The next iteration of APACHE will reportedly address outcomes across venues and allow automated outcome predictions for all hospitalized patients. The Multiparameter Intelligent Monitoring in Intensive Care II (MIMIC-II) database promises to promote research in epidemiology and clinical decision-rule creation by establishing a public-access, deidentified database.¹⁰² Caution is raised by a large Dutch study, however, where SMRs calculated using administrative data were unfavorable to those calculated using modified SAPS II clinical data, especially in institutions with a more severely ill population.¹⁰³

COMPARISONS AMONG MODELS

A number of papers have compared relative performance of the three most widely used ICU systems.¹⁰⁴⁻¹⁰⁶ Using data from 11,300 patients in 35 hospitals participating in the CALICO Project, APACHE IV, MPM₀-III, and SAPS II all showed adequate discrimination and calibration, with APACHE IV delivering the best predictive accuracy,

TABLE 181-6 Regional Application of Severity Scoring Models

| STUDY | COUNTRY | SYSTEMS | FINDINGS |
|------------------------------------|--|--|--|
| Arabi et al. ¹⁵⁶ | Saudi Arabia n = 969 | APACHE II MPM II ₀ and II ₂₄ SAPS II | Predicted mortality similar to that observed for all systems (SMR 1.0 to 1.09) Calibration best with MPM II ₂₄ Discrimination best with MPM II ₀ followed by MPM II ₂₄ , APACHE II, and SAPS; all ROC >0.79 |
| Capuzzo et al. ¹⁵⁷ | Italy Single center n = 1721 | APACHE II SAPS II | ROC area >0.8 both models Mortality in high-risk patients overpredicted by SAPS II and underpredicted by APACHE II |
| Katsaragakis et al. ¹⁵⁸ | Greece Single center n = 661 | APACHE II SAPS II | Good discrimination but poor calibration with both models Better performance with APACHE II |
| Livingston et al. ⁸¹ | Scotland 22 centers n = 10,393 | APACHE II APACHE III UK APACHE II MPM II ₀ MPM II ₂₄ | Discrimination adequate (ROC areas 0.74 to 0.795) Observed mortality significantly different from that predicted by all systems APACHE II had best calibration followed by MPM II ₂₄ and SAPS II |
| Markgraf et al. ⁷² | Germany Single center n = 2661 to 2795 | APACHE II APACHE III SAPS II | Observed mortality higher than predicted by any model Worst discrepancy with trauma, respiratory, neurologic, and renal disease Best calibration with APACHE II ROC area >0.8 all models |
| Moreno et al. ¹⁵⁹ | Europe 89 centers n = 16,060 | MPM II ₀ SAPS II | Discrimination adequate (ROC 0.822 for SAPS II, 0.785 for MPM ₀) Both models overestimated risk of death Large variations across subgroups of patients |
| Nouira et al. ¹⁶⁰ | Tunisia 3 centers n = 1325 | APACHE II MPM II ₀ and II ₂₄ SAPS II | Observed mortality higher than predicted except with MPM ₀ Good discrimination, poor calibration for all models |
| Tan et al. ¹⁶¹ | China (Hong Kong) Single center n = 1064 | APACHE II SAPS II | Discrimination good (ROC area 0.87 to 0.88) but calibration poor Both models overpredict mortality |
| Metnitz et al. ¹⁶² | Austria 22 ICUs n = 2060 | SAPS 3 | Original SAPS 3 overestimated mortality even with Central and Western Europe equation Calibration improved with customization |
| Poole et al. ¹⁶³ | Italy 147 ICUs n = 28,357 | SAPS 3 | Discrimination good Calibration poor—general and South Europe Mediterranean equations overestimated hospital mortality (SMR 0.73) |

albeit with longer data collection time.¹⁰⁷ Substantial variation occurred in ICU risk-adjusted mortality rates between ICUs, regardless of the model used.

Performance of three models based on 24-hour data (APACHE II, APACHE III-J, and SAPS II) was compared to that of three models based on admission data (MPM-II, SAPS III, and SAPS III-A using Australian coefficients) for 1741 patients in an urban university-affiliated teaching hospital in Australia.¹⁰⁸ SAPS II and SAPS III-A fulfilled predetermined calibration and discrimination criteria, APACHE II failed both criteria, and the remaining models discriminated well but overpredicted mortality risk. There did not appear to be an advantage in using 24-hour data versus data available at admission. The improved results with SAPS III-A versus SAPS III again underscores the benefit of customizing models with local coefficients. A Brazilian study found APACHE IV, MPM₀-III, and SAPS III to have good discrimination (AuROC 0.883, 0.840, and 0.855, respectively) but uniformly poor calibration leading to overestimates of in-hospital mortality.¹⁰⁹ Calibration was particularly problematic with SAPS 3, but APACHE IV and MPM₀-III also performed poorly at higher predicted mortality rates.

More recently, MPM₀-III, the ICOM_{mort} modification of MPM (also known as the National Quality Forum or NQF model), and APACHE IVa were compared based on a database of 174,001 ICU admissions from 2008 to 2012 at 38 U.S. hospitals.¹¹⁰ Only 109,926 patients (63%) met inclusion criteria for all three models. APACHE IVa offered the best discrimination and calibration and excluded fewer patients than

the other models. APACHE IVa overpredicted mortality by 1.5%, MPM₀-III overpredicted by 3.1%, and the ICOM-NQF model underpredicted by 1.2%. Calibration was best for APACHE IVa, which has implications for benchmarking using SMR when case mix varies among hospitals; this will be discussed below.

Table 181-6 summarizes the results of nine studies in which two or more of the risk-adjustment models were applied to a specific regional population. There is no consistent pattern to accuracy (discrimination), with examples of observed mortality higher than predicted, lower than predicted, as predicted, or predicted differently by different systems. There is also no consistent leader in calibration; it tends to be poor in many studies. Ratios of observed-to-expected mortality rates are influenced by case mix as well as by quality of care.¹¹¹

UTILITY OF SEVERITY OF ILLNESS INDICES

There are four major applications for severity of illness scoring systems:

1. Assessing ICU performance for quality improvement
2. Predicting and planning resource utilization and staffing
3. Comparing populations in clinical research
4. As one factor to consider in guiding individual patient care

Risk-adjusted outcomes data will be shared with a variety of “customers,” each of whom will have a different focus. In broad terms, clinicians and quality leaders will use data to drive improved care and

efficiency, while patients, governments, and payors will be more interested in comparing performance among institutions.¹⁵

QUALITY IMPROVEMENT AND BENCHMARKING

Meaningful evaluation of ICU performance must consider both severity of illness of the patient population and characteristics of the institution. *Benchmarking* refers to the process of comparing an individual unit's performance against established case mix-adjusted standards with similar ICUs or with the units' own data over time. Benchmarking need not be for morbidity and mortality outcomes alone; severity adjustment also helps explain variations in cost and ICU LOS.¹¹² Outlier LOS status is only partially predicted by severity of illness, and factors such as long ward stays before ICU admission and absence of an intensivist-directed multidisciplinary care team increase LOS.¹¹³

The mortality rate and LOS for patients transferred to a referral hospital is higher than that of nontransferred patients,¹¹⁴ and this referral bias¹¹⁵ has implications in profiling hospital quality. Medical patients transferred from another hospital have higher acute physiology scores but, even after adjustment for case mix and severity of illness, experience longer hospital and ICU stays and have more than twice the risk of hospital mortality compared with directly admitted patients.¹¹ These authors suggest that a referral hospital with a 25% transfer-in rate would suffer a penalty when undergoing profiling. Conversely, transferring patients to a tertiary care center has beneficial effects to the exporting hospital, since death is attributed to the receiving hospital.¹¹⁶ Transfer of mechanically ventilated patients from ICU long-term acute care (LTAC) facilities also significantly impacts reported mortality and LOS.¹¹⁷ Intrahospital transfers to a higher level of care after admission are also associated with excess mortality and LOS.¹¹⁸ As noted earlier, discharge practices affect risk-adjusted rates, with a greater impact on large hospitals and when in-hospital, rather than 30-day mortality rates, are considered.¹³

Factors unrelated to quality of medical care or patient severity of illness thus affect public reporting of SMR results. Does the benchmarking tool play a role? SMR was calculated for 47 ICUs at 36 U.S. hospitals using APACHE IVa and the ICOM-NQF models. Overall SMR was 0.89 using APACHE IVa and 1.07 using the NQF model. Disturbingly, the two models agreed on the significance and direction of the SMR only 45% of the time (Fig. 181-5). Units caring for more severely ill patients and with a higher percentage of patients receiving MV had the highest discordance.¹¹⁹ SMR and SMR rank position of ICUs also depend on whether the endpoint is in-hospital mortality or

FIGURE 181-5 ■ Standardized mortality ratio (mean and 99% confidence interval) for 47 ICUs evaluated using APACHE IVa (blue) and the ICOM-NQF (red) models. Over half of the performance assessments are discordant. (From Kramer AA, Higgins TL, Zimmerman JE. Comparing observed and predicted mortality among ICUs using different prognostic systems: why do performance assessments differ? *Crit Care Med* 2015;43:261–269.)

mortality at 1, 3, or 6 months after ICU admission.¹²⁰ In an age of outcome-driven reimbursements, these discrepancies are financially important, as well as ethically troubling.¹²¹ Public disclosure and rank-ordering ICUs on the basis of SMR or other metrics is thus highly problematic. Identifying hospitals with higher than expected mortality has no effect on market share¹²² and, reportedly, does not improve process-of-care indicators.¹²³ Benchmarking relative performance among ICUs should likely be replaced by comparing improvement in performance over time. Furthermore, discrepancies between observed and expected outcomes should primarily be a marker to prompt more careful review.¹²⁴

Case volume is an important consideration for evaluation and reporting. SMR should not be presented as a single number but rather as a range that encompasses the 95% confidence intervals based on sample size. Units with a low mortality rate require larger numbers of patients; this is well illustrated in a study by Dimick examining the problems with small sample size when evaluating surgical mortality.¹²⁵

Risk-adjusted mortality rates can be displayed over time; usually quarterly in smaller units and monthly in larger facilities. Standard statistical quality control charts and cumulative sums (CUSUM, a sequential technique) can be used to detect changes requiring investigation.¹²⁶ Exponentially weighted moving average control charts are said to signal the fastest compared with other types of risk-adjusted control charts.¹²⁷ For comparisons among institutions, funnel plots (Fig. 181-6) are preferable to league tables, as they incorporate volume-based control limits that reduce the risk of spurious interpretation inherent in a ranked list.¹²⁸ Other investigators have argued that funnel plots have difficulty identifying outliers with small volumes, while identifying divergence of statistical, but not clinical, importance when the numbers are large.¹²⁹

PREDICTING AND PLANNING RESOURCE UTILIZATION

The Therapeutic Intervention Scoring System (TISS) was developed as a method for quantifying patient care and severity of illness.¹³⁰ TISS was supplanted as a prognostic tool by the newer scoring systems once it was realized that application of technology depended on local availability and local practice. TISS is now used primarily to quantify nursing workload and costs.¹³¹ The Rapoport-Teres graph (see Fig. 181-4) displays MPM risk-adjusted mortality on the x-axis and resource use (LOS) on the y-axis.⁷⁸ Similar displays are possible using other risk adjustment systems.

USE OF SEVERITY INDICES IN CLINICAL RESEARCH

Existing databases permitting severity adjustment make possible hypothesis-generating observations and conclusions about therapeutic choices in situations where randomized, prospective evaluations might not be permitted or funded. For prospective studies, severity scoring indices can be used to risk stratify the population before randomization, thereby reducing the number of patients recruited and thus the cost of clinical trials. Clinical studies have also used scoring systems as part of inclusion criteria and to show that control and study groups have similar disease burdens.¹³² Cytokine profiles correlate with APACHE and MPM scores in septic individuals¹³³; however, severity scores were not designed for this purpose, and calibration has not been assessed in the clinical trial population. There is the danger that inclusion of age and chronic health points may exclude younger, previously healthy patients from trial entry.¹³⁴

USES OF SEVERITY ADJUSTMENT FOR INDIVIDUAL PREDICTIONS

The short answer is that risk-adjustment models are designed for evaluating groups and not for determining care of individuals. The

Hospital mortality for ICU patients

**FIGURE 181-6 ■ Example of a funnel plot, using hypothetical data.**

The ratio of observed to expected deaths is plotted on the y axis, with number of deaths on the x axis. Two- and three-standard deviation limits are plotted, which helps identify two hospitals (A and B) as significant outliers ($P < 0.001$). Three hospitals (“high performers”) have significantly fewer deaths than expected. Note that the observed count relative to expected (similar to the SMR) is +50% (SMR 1.5) for the lowest volume hospital, which is still within the 95% confidence intervals. Hospital B has a lower SMR at 1.35 (+35%) but, due to volume, can be identified as a significant outlier. A template for generating funnel plots like this can be downloaded from <http://www.apho.org.uk/resource/item.aspx?RID=47242>. Accessed 2/9/15.

problems with using scoring systems for individual patient care decisions arises from attempts to apply a probability estimate, which may range from 0 to 1, to an individual for whom the result will be 0 or 1. No model is accurate enough to predict that a given patient will certainly survive or invariably die, so scoring systems alone cannot dictate decisions to direct or withhold therapy. Sequential risk estimates, an approach explored by APACHE,¹³⁵ MPM,³³ and SOFA,¹³⁶ improve prognosis by incorporating data reflecting patient response to therapy over time. Objective predictions of the need for next-day life support are used by APACHE III and IV to guide triage and discharge decisions.¹³⁷ Increases in organ dysfunction scores following admission generally carry a poor prognosis,¹³⁸ although others have reported limited ability of the SOFA or MODS tools to discriminate outcome.¹³⁹ A meta-analysis of 46 studies suggests that 3% to 7% of patients discharged from the ICU will die prior to hospital discharge¹⁴⁰; ICU readmissions in this same population were 4% to 6%.

Use of scoring systems to individualize therapy has not been well studied. Recombinant human activated protein C (rhAPC), now off the market, considered an APACHE II score higher than 25 as a criterion for drug administration based on post hoc subgroup analysis of the PROWESS trial.¹⁴¹ However, issues with this approach include wide variability in severity score between ICU admission and time of drug administration,¹⁴² the confounding effect of DNR orders,⁵¹ and bias against younger, previously healthy patients.¹³⁵ Further, an efficient emergency department may well stabilize the patients and lower the APACHE II score before arrival in the ICU.¹⁴³

Objectively calculated severity scores are not necessarily more accurate than physician or nurse intuition when dealing with individual patients.^{144,145} Accurate prognosis may be most difficult for patients with the highest risk of death. A multicenter study addressing the issue of medical futility found that divergent judgments on patient prognosis by doctors and nurses increased with higher SAPS II scores and longer ICU stays.¹⁴⁶ ICU physicians discriminate between

BOX 181-4**Potential Pitfalls in the Application and Reporting of Severity-Adjusted Outcome****DATA COLLECTION AND ENTRY**

- Inclusion of ineligible patients
- Missing variables and data management errors
- Substitution of available for properly timed data
- Transcription and data entry errors
- Improper communication between hospital clinical and risk adjustment applications
- Wrong diagnosis selected
- Administrative data reflective of clinical situation
- Deliberate “gaming” of the system—upcoding of comorbidities

MODELS

- Case-mix differences (critical threshold exceeded)
- Application to subsets of development population
- Changes in influence of variable with improving medical care
- Small clinical changes become large risk increments when continuous data are categorized.
- Lead-time bias

OUTCOMES

- Insufficient range of outcomes reported
- Use of proxy outcomes that inadequately reflect true status
- Patient lost to follow-up
- Chance variability masquerading as true difference
- Relationships of scores to resource utilization and costs reflect observed practice, not ideal

REPORTING

- Confidence intervals not reported
- Inadequate sample size
- Physician of record misidentified
- Computational errors
- Misapplication of group data to individuals
- Misinterpretation of statistical significance as clinical significance

survivors and nonsurvivors more accurately than SAPS II, MPM-I, or APACHE II.¹⁴⁵

APACHE, SAPS, and MPM scores are *specific*, having more than 90% ability to predict survival but are relatively *insensitive* in predicting death. Such information should not be taken as a rationale to rely on clinical judgment alone and forgo the use of formal scoring. The existing severity indices, despite their flaws, provide useful, objective information that can supplement clinical judgment for prognosis and triage, bearing in mind that patient autonomy and medical ethics also influence these decisions. Surrogates of critically ill patients generally appreciate reliable prognostic information but cope with unfavorable news in a variety of ways, including seeking information from other sources and avoiding or disbelieving prognostic information.¹⁴⁷

PITFALLS IN THE APPLICATION OF SEVERITY OF ILLNESS INDICES

The use (and abuse) of databases for profiling ICUs and/or individual physicians is growing, despite flaws in administrative databases and problems identified with the application of statistical models²¹ and physician profiling.¹⁴⁸ Assuming a properly developed model is applied, potential pitfalls in application fall into four major categories: data collection and entry errors,¹⁴⁹ misapplication of the model,^{11,47,58} use of mortality as the sole criterion of outcome, and failure to account for sample size and chance variability^{56,108,112} when reporting results (Box 181-4). Errors in the EMR tend to propagate and become immortalized in the absence of a data collector who might note and correct artifacts and out-of-range values.⁸ Upgrading hardware or software can lead to obscure errors. My personal experience in this regard involved bedside monitors where the arterial waveform could be labeled “ART” or “ABP” depending on nurse preference. Months after a software upgrade,

investigation of an increasing ICU SMR finally disclosed that only one field was automatically imported into the APACHE system; missing the other resulted in a default situation where abnormal blood pressures were not credited to the APACHE score, thus reducing expected mortality and increasing the SMR.

Determination of the diagnosis is prone to bias,¹⁵⁰ but using a system that is blind to diagnosis will be inaccurate if case mix is markedly skewed.⁴⁷ Less obvious is the fact that many models start the “clock” with ICU admission, the timing of which is not standardized¹⁵¹ and frequently influenced by local conditions such as ICU bed availability.¹⁵² ICUs also do not function in isolation in the process of care,¹⁴⁴ and the growing trend toward aggressive use of step-down facilities and off-site chronic ventilation and rehabilitation units raises the question of whether hospital mortality is valid when patients may be transferred to other facilities alive but are still technology dependent.^{13,153} The issue of lead-time bias (pre-ICU stabilization) requires consideration; assessment is further complicated for patients with multiple ICU admissions,¹⁵³ whose second ICU admission during a single hospitalization is frequently excluded from subsequent analysis.²⁶ Which ICU stay, for example, should be counted for a patient who has ICU observation after an uneventful vascular procedure and then develops complications requiring ICU readmission on the fifth post-operative day? It is increasingly necessary to evaluate the performance of an ICU system, which includes pre-ICU, ICU, and post-ICU care. Models now in development will address outcomes across the entire arc of care.

CONCLUSION

APACHE, MPM, and SAPS are highly developed, prospectively validated tools useful for comparison of ICU performance in the care of groups of patients. Specialized models are available for burn, trauma, sepsis, cardiac surgical, and pediatric patients. When used as intended, these models allow stratification of patients for performance assessment, utilization management, clinical research, and dissemination of outcome results. Important implementation considerations include careful data collections, appropriate matching of the model and the population under study, and use of proper sample sizes and CIs in reporting results.

None of the models can perfectly predict the outcome for an individual patient.¹⁵⁴ However, this limitation is true of almost any test utilized in medicine and need not preclude the use of prognostic estimates for clinical decision support. Physicians must be alert to the limitations of severity-adjustment models in performance-based assessment, because case-mix differences, inadequate sample sizes, or systemic errors in data collection can generate erroneous conclusions about the quality of care. In the end, what is measured is less important than what is done with the measurement. The encouraging news is that despite an increase in severity of illness between 1988 and 2012, risk-adjusted hospital mortality for patients admitted to U.S. ICUs has decreased significantly, an observation that would have been impossible without the benefit of severity of illness scoring systems.¹⁵⁵

KEY POINTS

1. Stratification of outcome based on risk factors is necessary when comparing outcomes obtained by different institutions, intensive care teams, and treatment strategies.
2. Although mortality is readily defined and easily captured, it is insufficient as the sole measure of clinical outcome and does not capture other important endpoints such as complications, quality of life, or costs.
3. Administrative data are plentiful but are typically less reliable than carefully collected clinical information. The quality of administrative databases can be improved by including laboratory information.
4. Most outcome stratification models are developed empirically by performing univariate analysis of independent variables against a chosen outcome and are then refined using multivariate techniques.
5. Model performance is assessed by measuring discrimination (typically by ROC-curve area) and calibration (typically by goodness-of-fit procedures).
6. The standardized mortality ratio (SMR) is created by dividing observed by expected mortality rates. Values less than 1.0, if statistically significant, suggest performance better than

expected. SMR rankings can be problematic due to chance variation.

7. The Acute Physiology and Chronic Health Evaluation (APACHE II through APACHE IV), the Mortality Probability Models (MPM), and the Simplified Acute Physiology Score (SAPS) are well-developed, prospectively validated models useful in adult general critical care units. The Intensive Care National Audit and Research Center (ICNARC) and Veterans Affairs Intensive Care Unit (VA ICU) models are also available. Customized models are useful in highly specialized ICUs or when evaluating population subsets such as pediatric, trauma, or cardiac surgery patients.
8. Outcome predictions are intended for groups, not individuals. Mortality probability estimates range from 0 to 1.0, but an individual patient will either live or die. Mortality predictions also vary depending on when the data were geographically and temporally collected; results at ICU or hospital discharge do not necessarily correlate with 30-, 60- or 365-day results. Use of scoring systems to direct therapeutic choices has not been adequately studied, and risk-adjustment systems should never be the sole criteria for directing or withholding therapy in an individual patient.

The SAPS 3 study utilized an international population of 19,577 patients in 307 ICUs. Regional variation in outcomes occur, and SAPS 3 has customized admission equations for Australasia, Central/South America, Central/Western Europe, Eastern Europe, North Europe, Mediterranean countries, and North America. ROC area is 0.85 with satisfactory calibration.
- Higgins TL, Teres D, Copes WS, et al. Assessing contemporary intensive care unit outcome: an updated Mortality Probability Admission Model (MPM_{II}). *Crit Care Med* 2007;35:827–835.

- MPM III was developed on 124,855 patients admitted to 135 ICUs at 98 hospitals in the United States (94), Canada (3), and Brazil (1) between 2001 and 2004. It corrects the drift in calibration since MPM II and adds terms for "Full Code" resuscitation status at admission, and for the absence of any MPM II risk factor except age to account for better-than-expected outcomes in otherwise healthy elderly patients. Discrimination by ROC is 0.82, and the model calibrates well. Subsequent publications have prospectively validated the model, examined patient subgroups and updated the "Rapoport-Teres" resource utilization graph used by MPM and Project IMPACT.

- In total, 36,420 consecutive ICU admissions in 1999–2000 and a second cohort of 81,964 cases in 2002–04 were used to update the VA-ICU model. ROC areas were good. The VA-ICU population is overwhelmingly male (97.2%) and somewhat older. ROC area was 0.89, comparable to APACHE IV in this population, and better than MPM₂₄ II (ROC 0.84), SAPS III (ROC 0.86), or the SOFA score (ROC 0.81).
- Sinuff T, Adhikari NKJ, Cook DJ, et al. Mortality predictions in the intensive care unit: comparing physicians with scoring systems. *Crit Care Med* 2006;34:878–885.
- This analysis of observational studies (one using SAPS II, two using MPM II, six using APACHE II, and three computer models) found that ICU physicians and objective models have moderate accuracy in the first 24 hours of ICU stay, but that physicians better discriminate between survivors and nonsurvivors (physician ROC area 0.85 ± 0.03 versus 0.63 ± 0.06 for scoring systems). The conclusion that neither physicians nor scoring systems are sufficiently accurate to determine end-of-life decisions in the first 24 hours of ICU care is well supported by the data.
- Vincent JL, Opal SM, Marshall JC. Ten reasons why we should NOT use severity scores as entry criteria for clinical trials or in our treatment decisions. *Crit Care Med* 2010;38:283–287.
- Whereas the seemingly objective nature of scores make it tempting to apply their predictions to individuals, it is important to remember that these tools were designed for evaluating large groups of patients, not for individual prognosis or decision making. The authors point out that interobserver variability in score calculation, age bias, and issues with the starting time of critical care call into question the use of these scores for patient enrollment into clinical trials.
- Sefarian EG, Afessa B, Gajic O, Keegan MT, Hubmayr RD. Comparison of community and referral intensive care unit patients in a tertiary medical center: evidence for referral bias in the critically ill. *Crit Care Med* 2008;36:2779–2786.
- Patients referred to the Mayo Clinic medical ICU between 1996 and 2004 were more severely ill, had higher mortality and longer length of stay, and were more likely to receive an active ICU intervention compared with local patients. When adjusted for severity of illness, mortality was as expected. Unadjusted differences were not seen in the surgical ICU, although hospital mortality rate was lower in referral surgical patients. Referral bias likely occurs because of differences in prior care or the transfer process that are not captured by risk adjustment. This bias has potential impact on clinical trials.

- This report is for those who enjoy getting "under the hood" of risk-adjustment models.
- Timmers TK, Verhofstad MHF, Moons KGM, Leenen LPH. Intensive care performance: how should we monitor performance in the future? *World J Crit Care Med* 2014;3:74–79.
- Mortality is a limited outcome; health-related quality of life is another important benchmark to be followed after ICU or hospital discharge. Items that we do not routinely measure at present (both clinical and nonclinical) should be quantified and addressed by future systems.
- Kramer AA, Higgins TL, Zimmerman JE. Comparing observed and predicted mortality among ICUs using different prognostic systems: why do performance assessments differ? *Crit Care Med* 2015;43:261–269.
- Two widely used contemporary models (APACHE IVa and the National Quality Forum-endorsed ICOM modification of MPM) were evaluated in a common dataset of 89,353 consecutive unselected ICU admissions from 2008–2013. SMR was assessed and compared for each of the 47 intensive care units. Surprisingly, the two models agreed on the significance and direction of the SMR only 45% of the time. Differences were most pronounced in units with a high percentage of mechanically ventilated and/or severely ill patients. Four hospitals were assessed as having inferior performance using the NQF model but superior performance using APACHE. In addition, two additional hospitals would have been stigmatized by NQF results while being acceptable using APACHE. This study highlights the risk inherent in stigmatizing hospitals when performance depends on the benchmarking system utilized.

Severity of Illness Indices and Outcome Prediction: Children

Anthony D. Slonim and Murray M. Pollack

Today's healthcare environment demands attention to evaluating care so that improvement efforts can be made. Evaluation efforts need to be systematic in their collection, analysis, and information use. Although it is important to draw attention to objective performance measures, information derived from an appreciation of the perspectives and expectations of stakeholders who experience the program under examination are also useful. However, for pediatric intensive care units (PICUs) that primarily include the patient and family, a broader group of stakeholders, including colleagues on the multidisciplinary team, nurses, physicians, therapists, pharmacists, and social workers, as well as regulators and payers who are all interested in the program's quality, should be included.

HISTORICAL PERSPECTIVE ON QUALITY

Quality in health care has received increased focus over the past several decades, beginning with Donabedian's influence showing that the fundamental concepts of structure, process, and outcome were as important to health care as they were to other industries (Fig. 182-1). Since then, focused efforts to advance the concept of quality in health care have been performed. In the early 1990s, a series of articles quantified adverse events and helped disentangle the elements of patient harm and its relationship to risk management. A few years later, President Clinton, through an executive order, chartered a commission to investigate the quality of health care more broadly. Despite these and a variety of other prominent efforts, discussions regarding the quality in health care remained relatively stagnant until the Institute of Medicine's (IOM's) series of reports. The first IOM report, "To Err Is Human," provided a wake-up call for the healthcare industry to consider how patients may be harmed. This was followed by "Crossing the Quality Chasm," which defined six "Aims for Improvement." These Aims included safety, effectiveness, equity, timeliness, patient centeredness, and efficiency and helped establish a framework through which clinical services, including those delivered to the critically ill child, could be evaluated.

The Institute for Healthcare Improvement (IHI), among other groups, became instrumental in providing clinicians with tools to help them focus on improvement work by defining and measuring what was to be improved and by when. Efforts aimed at improving the reporting and learning from adverse occurrences became noticed when President Bush signed the Patient Safety and Quality Improvement Act, which would become operationalized, in part, through Patient Safety Organizations several years later. In addition, Bush created the Office of the National Coordinator for Health Information Technology (HIT), which was intended to advance dramatically the use of electronic health records.

In 2009, when the nation was experiencing financial turmoil, President Obama signed the American Recovery and Reinvestment Act (ARRA) into law, which was initiated to stimulate the U.S. economy. Several important healthcare provisions were included in this legislation to advance Medicaid, HIT, funding for the National Institutes of Health Clinical Effectiveness Research, and health professions education and to provide an important clinical focus on wellness, prevention, obesity, and chronic disease. In 2010, the Affordable Care Act was

passed. This piece of legislation has created dramatic changes in the healthcare landscape. With healthcare reform taking hold, considerable advances including medical homes, accountable care organizations (ACOs), and pay for performance have gained additional significance and set the tone for healthcare quality for years to come. This has created and will continue to generate important opportunities and challenges for advancing care for critically ill children.

SYSTEMS OF CARE

Traditional engineering approaches focus on how systems work rather than on understanding the ways in which they fail or the effects of failure. There are several aspects of system design and maintenance that can affect the likelihood of failure. This is a fundamental distinction to how quality is viewed in health care. First, clinicians often approach quality improvement from the perspective of risk rather than the perspective of reliability. Mortality and morbidity conferences, peer review meetings, and root cause analysis all tend to focus on what went wrong in retrospect and the elements of failure, rather than on the system's reliability. Second, pediatric critical care clinicians function in complex systems of care yet have little training or experience in how to design and organize those complex systems to assure that the needs of the critically ill child are met. Routinely, providers will repetitively use work-arounds rather than redesigning processes to be safer and more efficient. Finally, in contrast to the engineering approach, clinicians are very interested in the effects of system failure, which in clinical parlance are the outcomes of care. While outcomes are important, several efforts in health care have also demonstrated the importance of managing the processes of care. The best examples of these efforts in pediatric critical care medicine are evidence-based clinical guidelines, checklists, and bundles of care, which represent tactical opportunities to specify how care should be delivered to arrive at the desired outcomes. Evaluating the systems of care depends on both methodologic and content-oriented analyses. The next sections will provide some important context in these arenas for evaluating pediatric critical care medicine.

DESIGNING FOR EVALUATION: METHODS

Program Elements

The ability to evaluate clinical services, including pediatric critical care services, depends on how well the evaluation program is built and implemented. When considering complex systems, it is often helpful to begin by identifying the focus areas for evaluation and improvement and prioritizing those based on the desired impact. Quality improvement and evaluation rely on four critical and interdependent functions: data and analytics, process improvement techniques, change management principles, and team facilitation (Fig. 182-2). Each one of these functions is important in its own right, but none of these is sufficient individually to accomplish successful improvement efforts. The use of *data* is fundamental for improving quality. Data should be objective, easy to measure and accurate and should establish a baseline of

FIGURE 182-3 ■ Quality fusion. A concept for reaching higher gains in quality improvement and sustaining them for longer durations.

with relevance to their patients. The use of this “quality fusion” approach provides the PICU team with a greater impact on the initiative under study and also important sustinment when attention is diverted to the next improvement project.

**DESIGNING FOR EVALUATION:
CONTENT**

Organizing the different content elements of quality began in the latter portion of the 1970s when Donabedian described his “Attributes of Health Care” (Table 182-1). Pediatric critical care medicine was a new discipline at the time, and health care was itself still trying to define *quality*. By the time the IOM released its framework on quality using the six Aims in 2001, pediatric critical care medicine had matured considerably. The IOM framework provided a useful method to organize the approach to healthcare quality in the PICU. Each of the Aims had relevance to the provision of critical care services (see Table 182-1).

The IHI’s Triple Aim has taken hold as an important mechanism for evaluating the quality function from a content perspective (see Table 182-1). The reason the Triple Aim is so important is that it provides a construct that allows for evaluating clinical care at the provider, unit, and population levels and unifies strategies for safety and quality improvement within the context of a more integrated and collaborative care delivery model. In addition to focusing on clinical and service quality, the Triple Aim incorporates efficiency as a third element of evaluating care and is useful as an approach that can be applied to individual patients, groups, and populations of patients as is the case with emerging ACOs. These analyses are instructive for advancing improvements in care directly and for research and training.

**Improving Patient Care: Service and
Clinical Quality**

Service Quality

Service quality often encompasses a number of terms, including *empathy*, *compassion*, *needs*, and *respect*, that reflect the focus of attention on the patient and family. Additional components that help establish priority areas for the care of individual patients include health literacy under which the provision of information, communication, and education falls; attention to physical comfort; emotional support by relieving fear and anxiety; and the involvement of family and friends. Although “service with a smile” is important in caring for

patients and families, this broad compilation of terms demonstrates that service quality is a much more comprehensive approach that requires processes of care to be redesigned around the needs of patients and their families and not around the needs of the care team. Both elements of service are important to the successful care of the critically ill child and their family. The Healthcare Advisory Board identified several broad types of service problems in specialty care (Table 182-2) that remain relevant to the PICU even a decade after their publication.

Admission to the PICU, especially when emergent and unexpected, is an anxiety-provoking and fearful experience for patients and their families. For parents, the anxiety is generated from the lack of parental control; the appearance and discomfort of the child, both emotionally and physically; and the difficulty in communicating with staff. The age of the parents and their ability to focus on problems and participate in care are associated with an ability to cope with a critically ill child. Coping strategies for parents also include an ability to be supported by the PICU healthcare team. A variety of needs, including emotional, physical, and spiritual, have to be addressed by this support system. This can be accomplished by providing accurate information, allowing ready access to the child, and encouraging

parents' participation in their child's care. For hospitalized children, anxiety and stress may manifest themselves in behavior problems, especially in those with repeated or prolonged hospitalizations, those who are critically ill, and those with underlying mood or psychological disorders.

If family members perceive that emotional support is inadequate, their satisfaction with the experience and, more important, their long-term viability and cohesion as a family unit are at risk. Most families are satisfied with the care their children receive in the PICU and are particularly complimentary about the skill and competence of the nursing staff, as well as the compassion and respect shown toward their children, especially with regard to pain management. Attention to adequate pain and anxiety control is an essential component of the care of critically ill pediatric patients. Pain control addresses a fundamental need and is a compassionate practice that helps allay parents' anxiety and improve coping. The environment of the waiting area and the frequency of physician communication were both identified as detracting from parents' satisfaction with the PICU experience. The family's ability to function after the ICU admission of a child is dependent not only on their satisfaction but also on the severity of the child's illness, the duration of hospitalization, and the location of the hospital.

A customer service focus addresses such issues as wait for diagnostic testing or surgery. The healthcare providers' inattention to the flow of patients shows a lack of respect for patients and their families and can compromise the trust in the provider-patient relationship. Service quality can also extend beyond customer satisfaction to include patient outcomes. The ICU is a valuable resource for critically ill patients, and if ICU resources are not available when patients need them, adverse outcomes are possible. In this circumstance, the redesign of clinical processes has a direct effect in assuring that patients get services when and where they need them. For example, a child who experiences a cardiac arrest in the radiology suite is dependent on the ability of the institution to provide quick and definitive care in radiology rather than waiting to transport the patient to the ICU and delaying necessary therapies.

Clinical Quality

Clinical quality includes patient safety, clinical effectiveness, and efficiency in care. Although efficiency often points to lean processes, it also includes an approach that serves to minimize cost during the provision of care. Considerable focus relates to the "value proposition" in health care. Value is improved if quality for a given level of cost is improved. This is important, particularly when the evaluation frame shifts from individual patients to populations of patients.

Safety

Since the IOM's report on medical errors and patient safety highlighted the problem of iatrogenic injury in hospitalized inpatients, numerous stakeholders have begun to focus on reducing medical errors as a means of improving patient safety and reducing the harm associated with the delivery of health care. Adverse patient occurrences are inevitable in the high-risk environment of the PICU, but interventions aimed at reducing these adverse events can be designed once one understands how to evaluate clinical programs, the types of errors that may occur, and the circumstances that can contribute to them.

System Design as a Contributor to Safety Problems

The PICU environment may itself be an independent contributor to patient safety. Two characteristics contribute to the likelihood of errors in the PICU. The first is complexity, or the degree to which system components are specialized and interdependent. Complex systems are more prone to errors. The second characteristic is coupling. Tightly coupled systems have no buffer, and sequences are fixed, whereas loosely coupled systems can tolerate delays or variations in sequencing. Communication errors, equipment failures, system failures, and problems with teamwork are all associated with

complex and tightly coupled systems and can contribute to an unsafe environment in these settings. Equipment failures are an obvious and often unavoidable problem related to patient safety. However, communication failures, system failures, and teamwork problems can enhance the likelihood of errors and prevent an appropriate mitigating response when they occur. Appropriate attention to the physical layout and mechanisms for delivering care are important to ensuring a safe environment in the PICU.

Error Classification

Different classification schemes for medical errors have been developed, with some being easier to understand than others. Identifying critical incidents provides opportunities to make system improvements. However, system improvements may be limited unless there is a culture in which providers are held accountable for risky behaviors in the care process. This "Just Culture" approach provides a mechanism for accountability in the arena of patient safety. The IOM categorized medical errors based on their diagnosis, treatment, prevention, communication, and equipment failures. These categories have proven to be relevant for evaluating pediatric critical care services.

Several types of treatment errors also have relevance for the PICU. Medication administration errors occur frequently in the treatment of critically ill children and provide considerably more opportunities for medication errors and adverse drug events (ADEs). The PICU is an important setting for ADEs. Specific medication classes are prone to errors, including sedatives, vasoactive infusions, and parenteral nutrition. Acquired infections are important contributors to morbidity, mortality, and cost in the PICU. Our knowledge of the incidence, prevalence, risk factors, costs, and methods of improving bloodstream infections in the PICU has allowed us to demonstrate how care can be improved when providers use data to drive system change.

Interventional procedures are an important component of pediatric critical care practice. They provide the intensivists with the means to address a child's failing organ systems, but they are also associated with risks. Procedural risks are associated with both the insertion and maintenance of these devices. PICUs can address their rates of adverse occurrences related to both the performance and maintenance of commonly performed invasive procedures such as central venous access, mechanical ventilation, arterial cannulation, and intracranial pressure monitoring. Collaborative efforts that share best practice methods of inserting and maintaining these devices can demonstrably improve the complications associated with these procedures. In the ICU, considerable evidence has been accumulated regarding prophylaxis for gastrointestinal stress ulcers, deep venous thrombosis, pressure ulcers, and other adverse events.

Clinical Effectiveness

Evidence-based practice incorporates the best research evidence with clinical expertise and patient values to achieve the best patient outcomes. The practice of critical care medicine is highly variable among practitioners and institutions. Efforts to reduce the variability in care are provided by implementing practice guidelines, the use of clinical algorithms, and checklists.

Private, governmental, and subspecialty organizations have developed numerous guidelines to reduce unnecessary variability in care. The American Academy of Pediatrics and the Society of Critical Care Medicine have developed guidelines and policy statements to help improve the care of critically ill children. Guidelines can be heterogeneous with respect to their creation. At one extreme, results from randomized controlled trials are incorporated into the care guidelines; at the other extreme, the consensus of a group of practitioners is all that is required. This is important, because the success of any practice guideline is dependent on its ability to influence physician decision making.

Several important components of these guidelines are worth mentioning, because they will ultimately contribute to the acceptance of

the guidelines by the practitioners of critical care medicine. First, the guidelines should be grounded in the existing evidence base from randomized controlled trials. Second, when the evidence does not exist, the authors should assemble a multidisciplinary group of clinicians and researchers to reach consensus regarding treatment options. This is done to minimize bias by any one group of practitioners or any one discipline. Third, and perhaps the most important, the guidelines should be considered a “work in progress” that helps identify current deficiencies, from a data perspective, so that future research initiatives can be used to further support these guidelines.

Improving the Cost of Care

Economics demands that healthcare resources be delivered in a cost-effective and efficient manner while not jeopardizing the quality. The achievement of specific outcome goals is a measure of an ICU's quality. Costs vary with outcome measures. Mortality rates, efficiency rates, LOS, rates of nosocomial infection and readmission, and the presence of a teaching program all impact expenses and reimbursement. The quality at a given level of cost determines the value of a commodity. In this case, the commodity is ICU care.

The value of an individual ICU is increased by its ability to achieve selected measures of outcome while keeping costs to a minimum. This is concordant with the concept of efficiency as an aim in the IOM's model of healthcare quality. Intensive care services are a commodity, and those units providing quality care at a reasonable cost, as judged by efficiency and a similar patient mix, will be most appealing. Lessefficient ICUs will need to optimize efficiency or have cost-containment strategies imposed on them.

From a microeconomic perspective, patients who are sicker require more services in the ICU, stay longer, are more likely to die, and cost more to be treated. This is not new information. However, to balance the issues of cost and quality, ICUs should identify same-strata best-practices ICUs with similar cost drivers (e.g., severity of illness) and operate under a philosophy of targeted benchmarking to achieve comparability up to a specified level. To accomplish this, clinical scoring systems are frequently used to control for case-mix variables (physiology, diagnoses, and so forth) and thus allow for standardized comparisons. The LOS has become a standard in benchmarking ICU performance and quality, and reducing LOS is one method of reducing cost, although, as a variable itself, LOS is subject to differences in measurement. The standardized LOS ratio is that of observed to predicted LOS and is an indicator of resource use, adjusted for severity. The standardized LOS ratio can be used to compare a particular unit's performance over time, but it can also be used to determine whether a particular ICU's resource use is above or below that of similar ICUs.

Another method of assessing the efficiency of resource use in the ICU is to evaluate unique ICU therapies, that is, those that are best delivered in the ICU, such as mechanical ventilation and vasoactive infusions. Individual ICUs and physicians differ in their monitoring strategies; therefore, monitoring technologies should not be classified as unique therapies. The benefits of this approach are that it allows physicians to determine the proportion of low-risk monitor-only patients and compares the number of high-risk critical care patients requiring unique ICU therapies. Excess bed capacity leads to a higher ratio of monitored to high-risk patients and reduces the efficiency of the ICU. Opportunities to evaluate admission and discharge criteria as well as throughput issues, resulting from the inability to transfer ICU patients because of a high hospital occupancy rate, may serve to improve an individual ICU's efficiency.

EVALUATION DOMAINS AT THE PROVIDER LEVEL

The IOM framework is useful as an organizing principle to understand the healthcare quality from the perspective of the discipline of pediatric critical care or the ICU. Providers, when thinking about their practice,

tend to think differently about the healthcare quality. They often think about the care that they, rather than the healthcare team or the ICU, provide. Providers believe that they provide safe, timely, and effective care that corresponds to the latest evidence. They believe in engaging the child and family in the care and in treating all their patients fairly regardless of their personal characteristics or ability to pay. Donabedian's constructs of structure, process, and outcome are helpful in assisting different providers in identifying their role in the provision of quality care to patients because they know what is available to them to provide care, they believe that they understand their work, and they think that they understand what they are trying to achieve (Table 182-3).

Structure

“Structure” is usually interpreted from a “bricks and mortar” perspective. However, while the walls, monitors, equipment, and other technologies are certainly important structural elements, they are insufficient for the optimal delivery of health care. The people, including the patients, families, and providers of all disciplines; their knowledge of the child; their expertise; and their collaboration are needed to effect the best outcomes. Important evidence has linked the organization of the ICU and its management as key determinants of outcome. Taken together, these elements are the structural components of ICU care to which Donabedian might refer (see Table 182-3).

Process

Clinical processes are the interactions between providers and their patients and providers with one another. There is evidence that highlights the importance of team performance, in addition to clinical performance, for the establishment of outcomes. While nurses, by virtue of their training, tend to be process focused, physicians often lack this skill. Thus, when asked to address process steps, such as implementing the vascular access bundle, nurses are comfortable with the detailed specification of the process, which can make a difference in outcomes over time. Attention to the key processes of care are becoming recognized as important in determining outcomes, and a number of checklists, guidelines, bundles, and pathways have been developed to assure compliance with the many specification limits established in clinical care.

Outcomes

Finally, outcomes represent the culmination of the healthcare experience. Physicians often focus on outcome measures as a result of their work. In the ICU, mortality is a traditional outcome measure that is important, quantifiable, and often discussed (see Table 182-3). There are other outcomes of relevance including the use of ICU-specific therapies, LOS, cognitive and physical outcomes, and morbidities arising from the episode of care (see Table 182-3).

A major challenge of pediatrics has been the development of well-defined morbidity measures that are rapid, reliable, and objective; measure the child's status at the time of testing; and are applicable to a broad range of ages in a variety of environments. Although in-depth testing such as neuropsychological methods remain the clinical standard, other methods applicable to all pediatric ages and sufficiently rapid to be used in large samples were needed. The Glasgow Outcome Scale score was adapted to children in the Pediatric Overall Performance Category/Pediatric Cerebral Performance Category scores, but sufficient interrater reliability was only achievable when neighboring categories were combined; therefore, using these scores in outcome studies risked requiring very large sample sizes to detect significant differences. The history of outcome studies in adult medicine demonstrated the value of scales such as the activities of daily living scale. Such a functional status measure would enable researchers to track the trajectory of disease and recovery and might enable us to project future functional status, resource needs, economic impact, and other effects

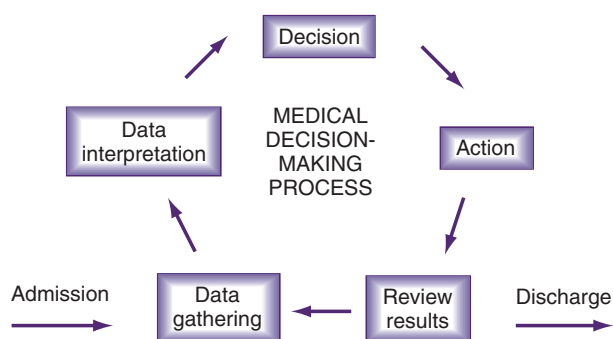

FIGURE 182-4 ■ Key elements of the medical decision-making process.

with patterns that are matched against a large mental library of similar conditions and patients. When the team is less experienced, the process is slow and prone to errors. The next step is decision making. Here, the physician may gather additional data by calling a consultant or ordering additional testing. If sufficient data have been gathered, the physician may formulate a medical treatment plan and reevaluate the plan's success as time progresses (see Table 182-3). The physician may recommend or perform a procedure, the outcome of which may assist with diagnosis or treatment. Nurses will incorporate their nursing diagnoses into the plan, and together the team will act with a comprehensive strategy for providing care. Finally, as the last step of medical decision making, the team must take action. A plan that is incoherent or not acted upon or a procedure or test that is thought about but not performed does not help the patient. These four steps allow the clinical team to think through and organize their work (see Fig. 182-4).

When evaluating the care at the provider level, there is often a deficiency in the available data by clinician. At this point, the best that many ICUs can do is to establish appropriate process steps in care and hold providers accountable for following these steps. Deviations from the process will occur because of differences in patient condition and case mix, but those deviations that are identified as random or reckless

can be dealt with through an environment that encourages a Just Culture. As evaluation tools at the provider level become more robust, so too will the evaluation of providers in the peer review process.

EVALUATION DOMAINS AT THE POPULATION LEVEL

Efforts in healthcare reform including the Patient Protection and Affordable Care Act (PPACA) have increased the focus on improving outcomes of care. These primarily include improving service and clinical quality and reducing cost. However, a major component of this legislation requires that populations be compared across these outcomes. The IHI's Triple Aim also differentiates itself by its applicability at both the individual and population levels.

A relatively new concept known as ACO assigns patients to specific providers to assure that appropriate care is delivered. Most ACOs exist for the adult Medicare beneficiaries and focus on primary care. It is likely that the total costs of care, including ICU care, will be included for these patients as these efforts mature. There are relatively few pediatric ACOs in the country today; however, it is likely that these will also expand as population-based care becomes more relevant.

Tools that allow the comparison of the severity of illness, both in the ICU and in the general population, are essential for assuring fair and equitable comparisons over time at the population level. It is possible that these new developments are likely to continue to advance innovative efforts of estimating disease burden and outcome, both mortality and morbidity, in populations of ICU patients.

CONCLUSION

Evaluating the current state of pediatric critical care requires a focus on both methods and content. From a content perspective, the Triple Aim has largely supplanted the IOM's Aim as the prevailing paradigm and can be applied at both the patient and population levels. Success in advancing quality in the PICU will depend on the ability to have providers appropriately focused on their discipline-specific processes of care in support of a much wider array of outcomes. What will follow is a better understanding of the influence that individual providers have on effecting these outcomes and enhancing provider-specific improvement activities for the benefit of patients.

Donabedian A. Explorations in quality assessment and monitoring: the definitions of quality and approaches to its assessment. Ann Arbor, MI: Health Administration Press, 1980.

Dr. Donabedian in one of his seminal works provides an approach and definitions for the evolution of quality assessment in an industry that has been imported and used repeatedly over decades in health care. This work is foundational to many of the efforts by the Institute of Medicine.

Kohn LT, Corrigan JM, Donaldson MS (eds). Institute of Medicine Committee on Quality of Health Care in America: To err is human: building a safer health system. Washington, DC: National Academies Press, 2000.

The first, and most controversial, of five publications by the Institute of Medicine that highlighted the dramatic and often quoted cost of life and financial expense related to medical errors in health care. This volume became a call to action for the healthcare system not only in the United States but also around the world to address the silent epidemic of medical errors that occur in the provision of healthcare services.

Institute of Medicine Committee on Quality of Health Care in America. Crossing the quality chasm: a new health system for the 21st century. Washington, DC: National Academies Press, 2001.

The second publication in the Institute of Medicine series that provided a framework to organize the quality initiatives into the six Aims including safety, efficiency, patient centeredness, equity, timeliness, and equitable. This framework has been used by countless organizations to organize the quality agenda and provide a roadmap to making sustainable improvements.

Slonim AD, Pollack MM. Integrating the Institute of Medicine's six quality aims into pediatric critical care: relevance and applications. *Pediatr Crit Care Med* 2005;6:264-269.

This manuscript applies the Institute of Medicine framework to the context of pediatric critical care medicine. The manuscript provides an overview of each of the Aims and specific examples that are relevant to pediatric critical care providers and academicians.

Slonim AD, Pollack MM. An approach to costs in critical care: macro versus microeconomics. *Crit Care Med* 1999;27:2286-2287.

This manuscript provides an approach that helps to inform the organizational structure of "macro" and "micro" within healthcare. It is a useful approach for evaluating not only costs but also quality. The

use of the macro- and micro-system theory was advanced by Drs. Nelson and Bataldan and applied subsequently in a variety of settings and contexts.

Marcin JP, Slonim AD, Pollack MM, et al. Long-stay patients in the pediatric intensive care unit. *Crit Care Med* 2001;29:652-657.

This manuscript highlights an important population of patients, children who are outliers for length of stay that suffer from both quality- and cost-related problems. It builds on an often conceived notion that a minority of patients and their demographics are responsible for the majority of health-related cost and quality concerns. This manuscript applies this approach to children with critical illness to help the industry better understand how few children can have care requirements that exceed the norms established for population inliers.

Steinbrook R. Health Care and the American Recovery and Reinvestment Act. *N Engl J Med* 2009;360:1057-1060.

This manuscript provides an overview of the American Recovery and Reinvestment Act (ARRA) and its relationship to healthcare. Although healthcare reform under the Obama administration is often considered to have started with the Patient Protection and Affordable Care Act (PPACA) in 2010, ARRA had a significant role in setting the stage from a financial incentive perspective so that PPACA could be implemented.

IHI Triple Aim Initiative. Available at: <http://www.ihi.org/Engage/Initiatives/TripleAim/pages/default.aspx>. Accessed on April 4, 2015.

The Institute of Medicine (IOM) had a major role in identifying the problems related to healthcare quality and organizing the work that needed to be accomplished. The Institute for Healthcare Improvement (IHI) has been an important participant and thought leader in assisting healthcare organizations with actually getting the work done. The IHI has conceptualized the "Triple Aim" that has largely supplanted the IOM's Aims as the prevailing paradigm for healthcare quality in the nation. This website provides an overview and many of the improvement efforts framed within this context.

Despite an increase in the incidence of critical illness syndromes such as severe sepsis and acute respiratory distress syndrome (ARDS), improvements in supportive care have resulted in improved survival.¹⁻³ Of approximately 6 million adults admitted to intensive care units (ICU) in the United States each year, more than 4.8 million survive.⁴ Traditionally, the focus has been on reducing short-term mortality. As more individuals survive their initial episode of critical illness, the goals of critical care extend beyond short-term mortality, and clinicians are challenged with the task of managing the consequences of those surviving critical illness.

Critical illness may result in long-term physical and neuropsychological dysfunction, ongoing healthcare utilization, and incurred costs.^{5,6} Although some survivors return to their precritical illness level of functioning and health, many others experience lasting impairments in cognition, mental health, and physical health or quality of life⁷ (Fig. 183-1). Any new impairment in one or more of these domains is termed *postintensive care unit syndrome* (PICS).⁸

In this chapter, we review the advances in our understanding of long-term outcomes after critical illness. Most literature focuses on long-term outcomes after acute lung injury and severe sepsis. We describe the epidemiology, risk factors, clinical manifestations, management, and outcomes for each domain of PICS.

COGNITIVE IMPAIRMENTS AFTER CRITICAL ILLNESS

Critical illness frequently results in new cognitive impairment, including deficits in memory, attention, and concentration.⁹⁻¹² The domains impaired in ICU survivors likely depend on the nature of the insult and its treatment as well as the presence of any preexisting neurologic abnormalities and individual characteristics such as age or comorbidities. A longitudinal cohort study in older adults who did not have premorbid neurocognitive impairments or dementia assessed neurocognitive function prior to and following acute care or ICU hospitalization.¹³ Individuals hospitalized for acute illness had a greater decline in neurocognitive function and new incident dementia than those not hospitalized. This finding suggests that acute or critical illness causes an abrupt decline in neurocognitive function that is not due to premorbid neurocognitive problems. A second study in patients with sepsis confirmed these findings. The Health and Retirement Study followed more than 27,000 older Americans, for whom neurocognitive function was assessed both before and after severe sepsis.¹⁴ Patients with severe sepsis developed new substantial and persistent neurocognitive impairment. Thus, factors associated with acute or critical illness may be causally related to neurocognitive decline in older critically ill patients.^{14,15} Similarly, Pandharipande et al. reported that a broad case mix of ICU survivors had important neurocognitive dysfunction comparable with mild dementia or moderate traumatic brain injury 1 year after their critical illness. This cognitive disability was present across different patient groups.¹⁶

The etiology of neurocognitive impairments is likely due to various factors that interact dynamically with preexisting and genetic variables to produce adverse outcomes. Current data suggest that unfavorable neurocognitive sequelae are not related to illness severity scores, age, smoking, or alcohol abuse. For example, neither length of ICU stay, Acute Physiology and Chronic Health Evaluation II scores, duration

of mechanical ventilation, and tidal volume nor days receiving sedative, narcotic, or paralytic medications are associated with neurocognitive impairments in critically ill ARDS survivors.¹² Thus, acute illness severity alone does not explain neurocognitive impairments experienced by ICU survivors. Possible pathophysiologic mechanisms include hypoxemia, cumulative use of sedatives or analgesics, hypotension, delirium, hyperglycemia, and sepsis and inflammation.^{10,17-19}

Early identification of cognitive impairment should, in theory, expedite appropriate evaluations and treatment. Evaluation for cognitive dysfunction in the critical care setting must be brief, easy to administer, and widely applicable.²⁰ However, currently available tests such as the modified mini-mental state examination and Montreal Cognitive Assessment are not validated to predict long-term cognitive dysfunction.^{20,21}

Management strategies to preserve cognitive function have been promoted, although strong evidence does not exist to support their use. These include screening for and minimizing delirium, reducing sedation, providing sedation interruptions, and preventing and mitigating risk factors such as hypoglycemia, hyperglycemia, hypoxemia, and hypotension.¹⁰

PSYCHIATRIC SEQUELAE OF CRITICAL ILLNESS

Psychiatric disorders, including depression, anxiety, and posttraumatic stress disorder (PTSD), are common among critical illness survivors. For instance, in a systematic review, Davydow and colleagues reported that 28% of ICU survivors had clinically significant depression.²² Similar to cognitive dysfunction, acute illness severity at ICU admission did not predict the development of post-ICU depression. Early post-ICU depressive symptoms were a strong risk factor for subsequent depressive symptoms, and post-ICU depressive symptoms were associated with substantially lower health-related quality of life (HRQoL). Compared with the population with general critical illness, post critical care depression seems more pronounced in ARDS patients.^{23,24} Risk factors associated with depression in this patient population include longer duration of mechanical ventilation, length of ICU stay, hypoglycemia, and cumulative sedation use.²³ Another study identified alcohol dependence, female sex, and younger age as risk factors for depression at 1 year in ARDS survivors.²⁵ The predictors of anxiety at 1 year included the ratio of arterial oxygen tension to inspired oxygen fraction and duration of mechanical ventilation.²⁵ The observed depression and anxiety post ICU treatment are likely multifactorial, and further study will be needed to better understand patient predisposition, illness, and treatment-specific determinants of affective morbidity and appropriate tools for diagnosis and monitoring.

Several studies have examined the relationship between critical illnesses and the development of PTSD. Schelling et al. were the first to introduce the concept of PTSD resulting from critical illness and traumatic experiences in the ICU.²⁶ Among their cohort of 80 long-term ARDS survivors, almost one-third reported impaired memory, nightmares, anxiety, and sleeping difficulties after ICU discharge, with a PTSD prevalence rate of 28%.²⁶ A meta-analysis of prevalence, risk factors, and prevention/treatment strategies for PTSD symptoms in critical illness survivors reported clinically important PTSD symptoms in approximately one-fifth of critical illness survivors at 1-year

FIGURE 183-1 ■ Conceptual model describing chronic health status before and during critical illness and the trajectories of health during recovery. **A**, Health status trajectory prior to critical illness. **B**, Health status during the acute phase. Health status often worsens during this phase because of organ dysfunction. **C**, Trajectories during recovery. These include no change in trajectory compared with **A** (C1), slow progressive worsening (C2), relapsing (C3), and rapidly progressive (C4) health status. (Modified from Yende S, Iwashyna TJ, Angus DC. Interplay between sepsis and chronic health. *Trends Mol Med* 2014;20:234–238.)

follow-up.²⁷ Patients with underlying psychiatric comorbidities, benzodiazepine use, or early memories of frightening ICU experiences had the highest prevalence of PTSD.²⁷ In European studies, the use of an ICU diary was associated with a significant reduction in PTSD symptoms, whereas a self-help rehabilitation manual or nurse-led ICU follow-up did not reduce PTSD symptoms at 6 months.²⁷ Other interventions such as administration of stress dose steroids to antagonize the stress response and thereby alter traumatic memories are speculated to reduce psychiatric sequelae in critical illness survivors.²⁸

CRITICAL ILLNESS-ASSOCIATED NEUROMUSCULAR DYSFUNCTION

ICU-acquired weakness is common in patients with ARDS and other complex critical illness. Regardless of disease process, muscles and nerves are injured, resulting in prolonged mechanical ventilation and poor functional outcomes. Previous research has highlighted the concept of a continuum of weakness that begins with muscle injury documented within hours of mechanical ventilation²⁹ and may persist with incomplete recovery for years after ICU discharge. Muscle weakness and impaired function constitute an important morbidity of severe critical illness.³⁰

Critical Illness Polyneuropathy

Clinically, critical illness polyneuropathy (CIP) primarily manifests itself as a mixed sensorimotor neuropathy. CIP is very common in patients with systemic inflammatory response syndrome and sepsis, with an occurrence of 70% to 100% of longer ICU stay patients.³¹ It affects the limb and respiratory muscles, whereas facial muscles are usually spared.³¹ Limb involvement is symmetric and most prominent in the proximal muscle groups and in the lower extremities. Detection of the true incidence of CIP is complicated by lack of consensus on surveillance, timing, and nature of testing and limitations to testing because of patient sedation or poor cooperation, formal definition, and diagnostic criteria.³² Weakness may initially be absent or difficult to detect clinically in these patients, but subsequent electromyography

testing will demonstrate abnormalities showing an initial primary axonal degeneration of the motor neurons, followed by the sensory neural fibers, and this coincides with acute and chronic changes of denervation noted on muscle biopsies in affected patients.³³

In sepsis, the pathogenesis of CIP is linked to a perturbation in the microcirculation, with resultant axonal injury and degeneration. There is also evidence for a disruption of nerve action potential, which may be reversible over the course of the disease.³⁴ Other risk factors associated with the development of CIP include hyperglycemia, and tight glycemic control has been shown to reduce the incidence of CIP in critically ill patients.^{35–37} The exact pathophysiologic link between glucose control and neuroprotection remains unclear but may involve preservation of mitochondrial functioning, calcium homeostasis, or modulation of nitric oxide production.^{34,38–40} In contrast to earlier associations between neuromuscular dysfunction and use of neuromuscular blockers, subsequent research data have not been able to corroborate that previous association.⁴¹ Data on the association between glucocorticoid use and weakness remain controversial; however, a national multicenter prospective trial in acute lung injury survivors reported a significant association between mean daily corticosteroid dose with impairments in physical outcomes after 1 year.⁴²

Critical Illness Myopathy

The reported incidence of critical illness myopathy (CIM) varies between 48% and 96% in prospective studies that have included muscle biopsy as part of their diagnostic evaluation.³² Pathologically, CIM is characterized by a diffuse, nonnecrotizing myopathy associated with fatty degeneration of muscle fibers, fiber atrophy, and fibrosis.²⁹ This has been described in patients with sepsis and in those treated with corticosteroids and neuromuscular blockers. Patients clinically appear weak and paretic and are difficult to wean from the ventilator. They may be indistinguishable from patients with CIP. Muscle biopsy allows differentiation among these lesions.^{29,32}

The pathophysiology of CIM entails catabolism, inflammation, and derangement of membrane excitability. Protein catabolism and an increase in urinary nitrogen loss are observed in CIM.⁴³ Muscle biopsies in affected patients show low glutamine, protein, and DNA levels. There is evidence for the upregulation of the calpain, caspase-3, and ubiquitin proteolytic pathways in concert with an increase in apoptosis.^{43–45}

Oxidative injury is common in critically ill patients, and it may result in disruption of insulin receptor signaling in muscle, reduction in glucose availability, and impairment of myofibril growth and repair.⁴⁶ Preclinical data suggest that muscle inexcitability observed during the acute phase of CIM is due to inactivation of sodium channels.⁴⁷

Early Mobility and Rehabilitation

The results of studies examining the effects of physical rehabilitation on short-term outcomes in ICU patients have been mixed, and there is no evidence to suggest that it improves long-term outcomes. The heterogeneity of critically ill populations and our inability to risk stratify these patients because of the lack of detailed understanding of underlying pathophysiology may be a potential explanation for the conflicting results in studies examining short-term outcomes. Early mobility has been shown to be safe and feasible and to alter short-term outcome.⁴⁸ However, adoption into practice is lagging, as demonstrated by a less than 50% implementation rate among 500 surveyed U.S. hospitals.⁴⁹ Commonly cited barriers include equipment and staffing.⁴⁹

CRITICAL ILLNESS-ASSOCIATED MORBIDITY

Critical illness survivors face a substantially elevated mortality after discharge from the hospital, a problem best documented for severe sepsis. For example, we and others have shown similar rates of excess

postdischarge mortality among survivors of severe sepsis.^{50,51} In addition, the vast majority of severe sepsis survivors is either diagnosed with a new health condition or has worsening of existing health conditions.⁵¹ Persistent inflammation or a procoagulant state seen during recovery from sepsis^{52,53} may increase the risk of cardiovascular disease (myocardial infarction, stroke, and need for coronary revascularization),^{50,53} diabetes,^{54,55} and atrial fibrillation.⁵⁶ Indeed, severe sepsis is a complex disease process with a plethora of potential mechanisms to explain how different aspects of sepsis and the short-term care of patients with sepsis may drive late sequelae. Some of these pathways may be unique to sepsis while others may be shared with other acute illnesses. Further observational studies require sophisticated designs to isolate potentially causal pathways. In addition, the ultimate step will be to conduct experiments where patients are randomly assigned to alternative care strategies designed specifically to alter these pathways with the hope of improving long-term outcomes of sepsis.

■ CHRONIC CRITICAL ILLNESS

Patients who survive their initial acute illness but consequently experience persistent organ failures necessitating prolonged intensive care meet the definition of chronic critical illness (CCI).⁵⁷ This illness is characterized by high hospitalization costs, frequent postacute care use, and poor long-term survival.⁵ The clinical and financial burden of CCI is expected to increase in the coming years because of both an aging population and advances in the early management of critical illness resulting in more long-term survivors.^{58,59}

In a population-based sample of five U.S. states, we found that the prevalence of CCI based on a consensus definition has been increasing over time, with associated in-hospital costs exceeding \$25 billion per year.⁶⁰ These findings underscore the importance of CCI to the field of critical care, particularly for healthcare policy and planning. Spending on CCI is likely to rise further as the population ages, because the prevalence of CCI increases dramatically with age,⁶⁰ similar to other critical illness syndromes such as severe sepsis and ARDS.^{61,62} On the basis of age-related differences in patient preferences for intensive care near the end of life,⁶³ the prevalence of CCI may vary, necessitating a decision (either implicit or explicit) to undergo prolonged life support on the part of patients or their surrogate decision makers.⁶⁰

The most common initial diagnoses that lead to CCI were acute respiratory failure requiring mechanical ventilation and sepsis.⁶⁰ Both are characterized by an excessive proinflammatory state that can lead to prolonged organ failures, neuromuscular weakness, and neurocognitive dysfunction; all of these are the hallmarks of CCI.⁶⁴ This finding suggests that the early treatment of sepsis and acute respiratory failure is an important target for CCI prevention. By preventing organ failures early in the course of critical illness, novel treatments such as early mobility,⁶⁵ early resuscitation,² decreased tidal volumes,¹ conservative fluid management after shock resolution,⁶⁶ and avoidance of excessive sedation⁶⁷ may be powerful levers for stopping CCI before it occurs, minimizing the population burden of this syndrome. Hospital-acquired infections may contribute to mortality among hospitalized patients and to the burden of CCI.⁶⁸

■ QUALITY OF LIFE

Several studies have shown that severe sepsis impairs quality of life.⁶⁹ Each of the outcomes described earlier may affect the quality of life. Approximately a third of survivors of sepsis hospitalization at 6 months have significant impairments in various domains of quality of life. The impairments in cognition and physical function described earlier may persist, leading to problems in mobility and performing activities of daily living and disability. Furthermore, although many sepsis survi-

vors return home, approximately one-third require additional help at home or are in a skilled nursing facility, acute care hospital, or rehabilitation facility.

■ CAREGIVER AND FAMILY BURDEN IN CRITICAL ILLNESS

Caregiver outcomes and their interaction with ICU survivors have gained importance in understanding the effect of critical illness on the family unit.^{70,71} There is a considerable body of work evaluating these interactions in other medical conditions, such as stroke or cancer.^{72,73} These data show that caregivers who are challenged in their caregiving contribute to poor outcomes and threaten home care for survivors.^{74,75}

Studies indicate that the majority of ICU survivors who received long-term mechanical ventilation required the assistance of a family caregiver 1 year after their critical illness.⁷⁶ Providing such care may result in PTSD, emotional distress, depression, anxiety, and reduced HRQoL.⁷⁷⁻⁷⁹ In addition, caregivers experience significant burden because of a patient's physical and psychological dysfunction and lifestyle disruption associated with the challenges of managing complex care at home.⁸⁰

■ FUTURE DIRECTIONS

The findings that a large proportion of patients who survive critical illness have poor long-term outcomes, which may be attributed to critical illness rather than preexisting chronic health, have implications for endpoints of future clinical trials. Traditionally, primary endpoints included only mortality. Incorporating both morbidity and mortality in a primary endpoint, similar to endpoints used for stroke,⁸¹ is important.

Most interventions for critical illness were administered for brief duration, for days to weeks. Since the poor long-term outcomes may last for months, interventions that started in the ICU but continued for longer duration should be tested in future clinical trials.

Finally, future studies should understand the mechanisms underlying poor long-term outcomes. These translational studies can be conducted either in animals, by developing models that mimic human disease and studying long-term outcomes over several weeks, or in humans where cohorts are followed for several months after discharge and tissue samples are obtained longitudinally.

■ CONCLUSION

With the growth of intensive care and concurrent improvements in supportive care, patients are more likely to survive their initial episode of critical illness. Critical illness survivors subsequently face a wide array of problems, including developing functional deficits, neuromuscular and neuropsychological morbidity, and worsening of existing chronic diseases or development of new chronic diseases, which often result in permanent functional impairment. This results in ongoing high healthcare utilization and frequent hospitalizations.⁸²

In addition, there is growing recognition that the consequences of critical illness place substantial strain on families of ICU survivors, who often bear the brunt of ongoing complex informal home care.^{71,80,83} Only some of these adverse outcomes have been adequately studied, and specific interventions to prevent these outcomes have not been tested in clinical trials.

Future research needs to address the pathophysiology of consequences of critical illness (e.g., ICU-acquired weakness or neuropsychological dysfunction) to develop comprehensive rehabilitation interventions that incorporate the needs of patients and caregivers.

Natural and man-made disasters have always been a part of life and are occurring with increasing frequency. They create varied degrees of chaos owing to mismatch of resources and needs, and they place a huge burden on healthcare systems. Restoring an affected society to its preevent status requires extraordinary efforts and incurs substantial costs. Thousands of people are injured physically and emotionally as the result of such events, and their effects continue long after worldwide attention has disappeared.

The devastating events of September 11, 2001, in the United States, subsequent acts of bioterrorism, and emerging infectious disease pandemics have brought new challenges to the field of disaster management and multidisciplinary hazard mitigation. Even though war- and terrorism-related disasters have gathered much attention, natural disasters have occurred with increasing frequency over the past decades. This has been attributed to the growth of human population in geographically disaster-prone areas, rapid industrialization, and increasing exposure to toxic and hazardous materials (HazMat).¹⁻³

Analyses of the response of different healthcare systems to major disasters in the past have demonstrated the need for a more clearly identified planning process to attend to the response to multihazard events.⁴ This provides a basic understanding of common disaster scenarios and highlights the role of intensivists in the medical response to disasters. It is important for practicing critical care clinicians to keep in mind that their role is first and foremost as a first receiver rather than a first responder; well-trained intensivists may be of much greater value remaining in the hospital setting rather than quickly mobilizing to the field, where their lack of situational preparedness may make them more of a hindrance than an asset.⁵

BACKGROUND

Major disasters occur regularly and cause widespread human death and suffering. Over the past two decades, more than 3 million lives have been lost worldwide to major disasters. A total of 39,073 people were reportedly killed by disasters alone in 2001, with the decade's annual average of around 62,000. Even though the numbers of geophysical disasters such as earthquakes and volcanic eruptions have remained fairly constant, recent years have seen the highest number of weather-related disasters.⁶ As populations grow and occupy spaces that are vulnerable to different hazards, disasters will increase in severity and impact. Events since the September 2001 terrorist attacks have brought attention to the effects of man-made disasters on the healthcare system and the need to anticipate and plan for such low-probability, yet catastrophic, events. Although there is basic similarity in the response to them, each type of disaster presents responders with unique demands. After any disaster, healthcare systems are tasked with preventing excessive deaths, mitigating suffering, and dealing with an often overwhelming inadequacy of resources. Over the past few years, disaster medicine has grown into a unique specialty to deal with planning and preparing for such cataclysmic events. It shares a common ideal with public health: "greatest good for the greatest number."³

A fundamental part of designing a medical response to disasters is to coordinate with healthcare personnel across the hospital system so that they overcome natural differences associated with each group and maximize efficient use of scarce resources. Because the sickest of all

viable patients will require intensive care, critical care physicians can play an invaluable part in coordination efforts. In addition to their usual role of being caregivers for patients in the intensive care unit (ICU), intensivists will be expected to help in triage decisions, transport critically ill patients, and treat the multitude of injured in a rational order. They can also help by providing essential medical care at the actual disaster site via mobile ICU teams. It is thus important for critical care physicians to be familiar with the basics of disaster management, acquire organizational and leadership skills, practice delivery of unconventional critical care, and be familiar with different disaster-related medical syndromes.

TERMINOLOGY

Physicians and healthcare personnel should be familiar with the basic nomenclature and terminology in disaster medicine. Clear, common, and concise definitions are important to effective communication and evoking appropriate responses in disaster situations. Uniform use of terminology across healthcare systems provides a basis for analyzing and constructing an effective disaster plan and response by all responders.⁷ Controversies surrounding the definitions of *disasters*, *hazards*, and *casualties* are included in the discussions that follow.

The word *disaster* connotes a subjective assessment that has various meanings to different people and has an inherent bias, depending on the person using it. For example, a local, state, or federal "disaster declaration" implies commitment of financial and other resources. Similarly, a disaster in one community is not necessarily the same in another. Currently, there is no uniformly accepted definition for the word *disaster*.⁷ De Boer recognizes the lack of a meaningful definition for the word and instead proposes the term *medical severity index*.⁸ This term, however, has not gained sufficient acceptance for routine use. Different modifiers can lead to different definitions of the term *disaster*. They include the type of disaster, geographic area involved, timing, onset of the event, size of the community affected, baseline resources available, and physical, psychosocial, and economic injuries caused by the event. However, from a healthcare standpoint, the most important variable that defines a disaster is its functional impact on the healthcare facility.⁷ Despite various attempts to clear this confusion, the issue remains unresolved.^{7,9,10} What follows are the commonly used definitions in disaster medicine from a healthcare perspective:

Hazard. An event with the potential to cause catastrophic damage. It may be a "naturally" occurring phenomena, such as volcano eruptions, or "man-made," such as nuclear power plant accidents.¹¹

Emergency. A natural or man-made event that significantly disrupts the environment of care (e.g., damage to an organization's buildings due to severe winds, storms, or earthquakes), resulting in disrupted care and treatment (e.g., loss of utilities, such as power, water, or telephones, due to floods, civil disturbances, accidents, or emergencies within the organization or in its community); or resulting in sudden, significantly changed, or increased demand for the organization's services (e.g., bioterrorist attack, building collapse, or plane crash in the organization's community).

Disaster. A hazardous event causing physical, psychological, social, economic, or even political effects on a scale such that the stricken community needs extraordinary efforts to cope with it and often

outside help or international aid.^{9,10} Medical disasters form a subset of this category, in which physical and/or psychosocial injuries exceed the medical response capabilities of the community affected.

Casualty. Any person suffering from physical and/or psychological damage by outside violence leading to death, injuries, or material losses. Again, the word has no standard definition and is sometimes used to imply injury, death, or both. It may also bear financial implications, because federal reimbursement may be approved only for people classified as casualties.^{7,9,10}

Potential injury-creating event (PICE) system. A new system developed to overcome the differences in disaster nomenclature. It uses the functional impact on the healthcare facility as the only determining factor to define an “emergency” or “disaster.” It uses four modifiers to communicate the impact caused by the situation on the healthcare facility.⁷

Multicasualty incident. A hazardous event that, regardless of its size, is containable by local emergency medical services (EMS). From an operational standpoint, an event becomes a multicasualty incident when its impact exceeds the day-to-day response routine to the EMS. Adjustments within the local response system are required to cope with this demand without the need to request outside help (level 1 response).¹²

Mass-casualty incident. A hazardous event that overwhelms local response capability. It is likely to impose a sustained demand for health services rather than a short, intense peak typical of many smaller scale disasters. This may require a level 2 response (neighboring and regional resources are activated) or a level 3 response (state, interstate, and federal resources are activated in the rescue and recovery process).¹³

Hazard vulnerability analysis (HVA). The identification of potential emergencies and the direct and indirect effects these emergencies may have on the organization’s operations and the demand for its services.¹⁴

CLASSIFICATION OF DISASTERS

Natural disasters arise from the forces of nature and include earthquakes, volcanic eruptions, hurricanes, floods, fire, and tornadoes. In addition, infectious disasters can be classified as epidemic or pandemic. Man-made disasters are due to identifiable human causes and may be further classified as complex emergencies (e.g., terrorist attacks) and technological disasters (e.g., industrial accidents).¹⁵ Other classifications include those based on onset (acute vs. insidious disasters), predictability, duration, and frequency. From a public health perspective, disasters must be defined by their effect on people and the healthcare system. The concept of functional impact to the healthcare system is paramount.^{15,16}

The PICE system attempts to create uniformity to address the wide spectrum of situations.⁷ The two major aims of this system are to communicate both the operational consequences to a hospital or community and the type and amount of outside assistance needed. Four modifiers for an event are chosen from a standardized group of prefixes, and a stage is assigned (Table 184-1). *Column A* (first prefix)

TABLE 184-1 PICE Nomenclature

| A | B | C |
|---------|---------------|----------|
| Static | Controlled | Local |
| Dynamic | Disruptive | Regional |
| | Paralytic | National |
| | International | |

PICE, potential injury-creating events.

Data from Koenig KL, Dinerman N, Kuehl AE. Disaster nomenclature—a functional impact approach: the PICE system. *Acad Emerg Med* 1996;3:723–727.

describes the potential for additional casualties. For example, a finite number of people injured in an airplane crash is a “static event,” whereas an ongoing fire is a “dynamic” event. *Column B* (second prefix) describes whether local resources are sufficient (“controlled”) or overwhelmed. If they are overwhelmed, the two modifiers “disruptive” and “paralytic” indicate whether they must be simply augmented or totally reconstituted. Paralytic PICEs are the most daunting of all situations, and they can be either destructive or nondestructive (Table 184-2). *Column C* describes the extent of geographic involvement. The *PICE stage* refers to the likelihood that outside medical help is required (Table 184-3). This PICE model provides important concepts for disaster planners, researchers, and responders. Using this system, disasters can be described both prospectively and retrospectively. PICE is a valuable tool for use in planning and disaster mitigation, but the system warrants validation on a wider scale. It may also require further refinement to delineate the type of aid needed by an affected community.⁷ Regardless of the type of classification used to categorize disasters, certain unique features are associated with each type of disaster. It is important to understand the common effects of different natural and man-made disasters to predict their impact and plan effectively. Some common disaster situations are reviewed next.

TABLE 184-2 Paralytic PICE

| DESTRUCTIVE | NONDESTRUCTIVE |
|-------------------|---------------------|
| Bomb explosion | Snowstorm |
| Earthquake | Employee strike |
| Tornado | Power failure |
| Civil unrest | Water supply cutoff |
| HazMat spill | |
| Fire | |
| Building collapse | |

HazMat, hazardous materials; PICE, potential injury-creating events.

NATURAL DISASTERS

Earthquakes

Earthquakes are a model of a disaster that results in significant mortality,¹⁷ as can be seen in Figure 184-1. A homogeneous population well trained in both basic trauma and life support and the architectural design of the housing and public facilities of the stricken area are the two major determinants of outcomes for earthquake victims. The massive earthquakes in recent years in Turkey, Taiwan, Sumatra, Kashmir, Sichuan, and Haiti have shown us that a sound engineering design for earthquake resistance in civil structures such as schools and hospitals have a major impact on outcomes. In addition, urban earthquakes generate massive fiscal impact on the world in terms of reconstruction grants provided by wealthier countries for devastated urban areas. Moderately destructive earthquakes in the developing world usually cost up to \$10 billion in reconstruction; the needs of developing countries with urban earthquakes may cost an order of magnitude more.

Despite extensive experience and published literature dealing with medical response to earthquakes, the earthquake in Haiti shows that we are frequently doomed to relearn the lessons forgotten.

The Haiti earthquake occurred on January 12, 2010, and was of magnitude 7.0 on the Richter scale, resulting in some 230,000 mortalities and 1.5 million homeless. Let us consider first the military medicine response delivered, especially in the face of continuous exposure of the military medicine establishment to mass-casualty management in the wars in the Middle East.

Responders from the very experienced Israel Defense Forces (IDF) were air-deployed within 48 hours of the Haiti earthquake. This team had extensive experience over the years with international response and consists of 230 people. The team unpacked and built their portable hospital within 8 hours, and during 10 days of operation treated more than 1100 patients in a facility designed to provide 60 inpatient beds, including 4 intensive care beds and 1 operating room.¹⁸ Most of the

first wave of casualties presented with crushed limbs with open infected wounds, and the later arrivals presented with sepsis and poor chance of outcome. Despite the repeated experience from prior earthquakes showing that victims of crush syndrome and acute renal failure require emergency dialysis to prevent death, this facility relied on other international teams for dialysis. Their major dilemmas were practical implementation of the triage algorithm by military personnel to a civilian population. The simple priorities were urgency, resources available, and probability of saving life. Patients with brain injury, paraplegia due to spine injuries, or a low Glasgow Coma Scale score were immediately transferred to other facilities, since no neurosurgical capabilities were available. A triage panel of three senior physicians relieved individual physicians of personal accountability. Half of the intensive care capability was always dedicated to postoperative care, with the remaining two beds used for prolonged intensive care; only patients who were expected to stabilize within 24 hours were placed in these beds. The very early discharge policy permitted this facility to treat more than 100 patients per day.

Second, let us consider the response of the U.S. military, which had a considerable portfolio on providing disaster relief in catastrophic events such as the Indonesian tsunami that devastated Sumatra. The U.S. Naval Ship (USNS) *Comfort*, one of the hospital ships of the Military Sealift Command, was deployed as part of the mission termed *Operation Unified Response*. It started accepting casualties within 7 days of the earthquake. The ship is a 1000-bed facility that includes 75 ICU beds, blood bank, hemodialysis, pathology, physical therapy, morgue, and radiology with computed tomography and ultrasonography capability. It is staffed with 1000 active-duty U.S. medical personnel, including three physician intensivists, and it was allocated to stay up to 6 months.^{19,20} The first wave of casualties were critically ill trauma patients airlifted from field hospitals by U.S. helicopters. Within 72 hours, the *Comfort* admitted 254 patients, and the census rapidly increased to 430, more than a third of them pediatric cases. A team of six internists provided 24/7 coverage. Dozens of patients underwent mechanical ventilation simultaneously; the open-bay design did not allow for isolation, and the nurse-to-patient ratio was about 7:1. A large volume of hemodialysis was provided to patients with crush syndrome, leading to rapid depletion of dialyzers and dual-lumen dialysis catheters. The discharges exceeded admissions in about 2 weeks, and after a total of 629 admissions, the ship completed its mission. While the standard of care exceeded community expectations, the U.S. Navy personnel followed naval protocol and standards.

Third, let us consider the relearning of the lessons of civil-military collaboration in disaster response.²¹ A volunteer medical team with civilian personnel under the auspices of the international medical corps flew to the Dominican Republic and reached the Hôpital de l'Université d'Etat d'Haïti in Port-au-Prince after a long bus ride on January 17, 2010. There were more than 800 injured in the partially destroyed facility, with the primary diagnoses being crush injuries, compartment syndrome, infected fractures, and hemorrhagic shock. One physician and one nurse were covering up to 80 critically ill patients in the wards. An aftershock of 5.9 magnitude resulted in an exodus of casualties and higher rates of heat stroke in dehydrated hypovolemic patients exposed to tropical temperatures. Destruction of the prison system released 4000 criminals into the community, and no security was available until the arrival of a U.S. airborne infantry regiment. With the arrival of the USNS *Comfort* on January 20, evacuation of the most critically ill patients started, but a triage list developed rapidly, with ship facilities accepting preferentially complicated injuries, obstetric patients, and maxillofacial injuries. Patients with pelvic fractures, closed head injuries, complete spinal cord lesions, and mechanical ventilation cases were of too high acuity for the USNS *Comfort*. Family structures became fragmented, as separation of children from parents occurred. Yet the collaboration of civilian and military medical personnel was considered a success.

Next, let us consider the experiences of academic centers delivering care to victims of the Haitian earthquake on-site.²² The Miller School of Medicine of the University of Miami and Project Medishare had the

FIGURE 184-1 ■ Deaths from earthquakes since 1900. The toll of the Haiti quake is more than twice that of any previous magnitude 7.0 event and fourth worst since 1900. (From Hough SE, Bilham R. After the earthquakes: elastic rebound on an urban planet. New York: Oxford University Press; 2006; and Bilham R. The seismic future of cities. *Bull Earthq Eng* 2009;7:839-887.)

advantage of long experience of collaboration with Haiti and close geographic proximity, and they were able to provide emergency relief within 20 hours. Within 8 days, they were able to establish a field hospital at the city airport, and by January 21, 140 patients were transferred into the upgrade facility. The well-organized command center with satellite links for telephone and Internet access was available. A joint adult-pediatric triage team accompanied by Creole-speaking medical staff of Haitian origin was used. Multiple surgeries were performed under local peripheral nerve blocks, with guillotine amputations being frequent. The highest acuity patients were transferred to the IDF field hospital or the USNS *Comfort*. The command center eventually provided psychiatrists to manage the posttraumatic stress syndrome and a buddy system for the follow-up support.

Finally, one must consider the critical care response from New York City. Although many small teams and a large volume of supplies were dispatched, an organized response was delivered under the leadership of Dr. Ernest Benjamin, division chief of critical care in surgery at Mt. Sinai Hospital. Dr. Benjamin arrived in Port-au-Prince 3 days after the initial event, and after rapid assessment of needs and resources, organized the deployment of the 27-member critical care team to his home country, which arrived on January 20. The team remained on-site for 2 weeks and was responsible for postanesthesia and postoperative care delivery, with Dr. Benjamin being deputized as the director of critical care and recovery at the national hospital. The home institution effectively secured anonymous donations of private jets able to transport the team personnel and some 3000 pounds of medical supplies per flight. The team delivered intensive care with minimal technology but with kindness and dignity toward the suffering population. This was a truly integrated response with both language and cultural sensitivities and capabilities, which are very important in catastrophic situations that will take decades for the local population to recover from.²³

Experience in managing catastrophic international disasters continues to accumulate with unfortunate regularity. The preceding discussion suggests that combinations of dialysis, orthopedic surgery, pediatric trauma, security, transportation, posttraumatic stress treatment, and cultural and language sensitivities are crucial in earthquakes. Disasters produce well-defined syndromes with well-defined mortalities. It is the recovery phase that continues to require persistence and improvement. One of the most experienced managers and thought leaders in disaster management, Dr. Eric Noji, enumerated the most important factors in public health after disasters: environmental health, epidemic management, immunization, controlling the spread of human immunodeficiency virus/acquired immunodeficiency syndrome, management of dead bodies, nutrition, maternal and child health, medical services, and thorough public health surveillance. It is a common error to deliver a few weeks of heroic quality care and then abandon the population to the ravages of destroyed infrastructure, including public health organization.²⁴

Volcanic Eruptions

A volcano is a hill or a mountain built around a vent that connects with reservoirs of molten rock below the earth's surface.²⁵ Different types of eruptive events occur, including pyroclastic explosions, hot ash releases, lava flows, gas emissions, and glowing avalanches (gas and ash releases). Lava flows tend not to result in high casualties, because they are easily avoidable. The "composite" type of volcano is associated with a more violent eruption from within the chimney. These eruptions are associated with air shock waves, rock projectiles (some with high thermal energy), release of noxious gases, pyroclastic flows, and mud flows (lahars). Pyroclastic flows and lahars are often fast moving and are the main cause of damage and deaths from volcanoes, as evidenced by the small eruption of the Nevado del Ruiz in Colombia that killed more than 23,000 people.²⁶ The release of ash and its subsequent rapid buildup on building structures can be substantial, causing them to collapse within hours. Ash is also responsible for the clogging of filters and machinery, causing electrical storms and fires, and interfering with

communications. Ash is a main cause for respiratory-related syndromes and conjunctival and corneal injury. A variety of toxic gases (e.g., carbon dioxide, hydrogen sulfide, sulfur dioxide, hydrogen chloride, hydrogen fluoride, and carbon monoxide [CO]) are released during eruptions, causing bronchospasm, pulmonary edema, hypoxemia, cellular asphyxiation, topical irritation of skin and other mucosal surfaces, and death.²⁷ Damage to health infrastructures and water systems can be severe. Problems related to communication (ashes cause serious interference) and transportation (poor visibility and slippery roads) are likely. On the basis of the initial assessment, various needs can be anticipated. Reducing the risk for vulnerable groups of being exposed to ash, raising awareness of the risk associated with ash (health and mechanical risk), and maintaining food security conditions over the long term (lava, ash, and acid rain cause damage to crops and livestock) can help limit suffering.²⁸

Hurricanes, Cyclones, and Typhoons

The large rotating weather systems that form seasonally over tropical oceans are variously named, depending on their geographic region of origin.²⁹⁻³¹ They consist of a calm inner portion called the eye, surrounded by a wall of rain and high-velocity winds. On the basis of central pressure, wind speed, storm surge, and potential destruction, their severity is graded on a scale of 1 to 5 (Saffir Simpson scale).³⁰ They are among the most destructive natural phenomena. Cyclones during 1970 and 1991 in Bangladesh claimed 300,000 and 100,000 lives, respectively, because of flooding.³² The most devastating hurricane ever to hit the United States occurred in 1900 at Galveston, Texas. It claimed an estimated 8000 to 12,000 lives.³³ The greatest damage to life and property is not from the wind but from secondary events such as storm surges, flooding, landslides, and tornadoes. Ninety percent of all hurricane-related deaths occur from storm surge-related drowning.¹ The most common injury patterns include lacerations (during the cleanup phase), followed by blunt trauma and puncture wounds. Late morbidity can be due to postdisaster cleanup accidents (e.g., electrocution), dehydration, wound infection, and outbreaks of communicable diseases.^{31,34} Data from Hurricane Katrina confirmed data from previous meteorological events. The leading mechanisms of injuries are fall, lacerations, and piercing injuries, with cleanup being the primary activity at the time of injury.³⁵ Resources may have to be provided for an extended period after the initial inciting event, and significant resources may have to be provided for patients with chronic medical illnesses.^{34,36}

Floods

There are three major types of floods: flash floods (caused by heavy rain and dam failures), coastal floods, and river floods. Together, they are the most common types of disasters and account for at least half of all disaster-related deaths.^{37,38} The primary cause of death is drowning, followed by hypothermia and injury due to floating debris.^{39,40} The impact on the health infrastructures and lifeline systems can be massive and may result in food shortages. Interruption of basic public services (e.g., sanitation, drinking water, and electricity) may result in outbreaks of communicable diseases.^{38,40} Another concern is the increase in both vector-borne diseases (e.g., malaria and St. Louis encephalitis) and displacement of wildlife (e.g., poisonous snakes and rodents).^{39,40}

Landslides

Landslides are more widespread than any other geologic event. They are defined as downslope transport of soil and rock resulting from natural phenomena or man-made actions. Landslides can also occur secondary to heavy storms, volcanic eruptions, and earthquakes. Landslides cause high mortality and few injuries. Trauma and suffocation by entrapment are common. Pending an assessment, needs can be anticipated, such as search and rescue, mass-casualty management, and emergency shelter for the homeless.^{41,42}

Pandemic 2009 H1N1 Influenza A Virus

Pandemic H1N1 2009 is a new strain of influenza A virus that was first identified in Mexico and the United States on March 18 and April 15, 2009, respectively. It originated from the quadruple reassortment swine influenza (H1N1) virus closely related to the North American and Eurasian swine lineage. However, this new virus circulated only in humans, with no evidence of transmission between humans and animals.

Within weeks, the virus quickly spread worldwide through human-to-human transmission. On April 26, 2009, the Strategic National Stockpile of the Centers for Disease Control and Prevention (CDC) began releasing 25% of the supplies in the stockpile for the treatment and protection from influenza.⁴³ On June 11, 2009, the World Health Organization (WHO) declared the 2009 H1N1 influenza a global pandemic, generating the first influenza pandemic of the 21st century, with more than 70 countries reporting cases of H1N1 infection. By June 19, 2009, all 50 states in the United States, the District of Columbia, Puerto Rico, and the U.S. Virgin Islands had reported cases of 2009 H1N1 infection. More strikingly, the CDC Emerging Infections Program estimated the number of hospitalizations and deaths in people aged 64 years and younger. The virus was most likely to strike children, young adults, and those with underlying pulmonary and cardiac disease. Pregnant women in their second and third trimester were also at high risk. Patients requiring intensive care had a remarkable prevalence of obesity.⁴³

Influenza vaccines are most effective not only to prevent but also to mitigate the severity of illness. The pandemic H1N1 influenza vaccine was promptly developed by the WHO and national authorities. A national influenza vaccination campaign was launched in the United States in October 2009, and the first H1N1 vaccine was made available at that time. Despite the rapid response of the authorities, developing countries in the Southern Hemisphere experienced delays and shortages of the vaccines. Thus, research and developmental work have been encouraging for developing a “universal” influenza vaccine that could provide efficacious cross-reactive immunity and induce broad protection against different variants and subtypes of the influenza virus.⁴⁴

Data show that about 8% of H1N1 patients were hospitalized (23 per 100,000 population); 6.5% to 25% of these required being in the ICU (28.7 per million inhabitants) for a median of 7 to 12 days, with a peak bed occupancy of 6.3 to 10.6 per million inhabitants; 65% to 97% of ICU patients required mechanical ventilation, with a median ventilator duration in survivors of 7 to 15 days; 5% to 22% required renal replacement therapy; and the 28-day ICU mortality was 14% to 40%.⁴⁵⁻⁵¹ Critical care capacity is a key element of hospital surge capacity planning.¹⁰ The proportion of ICU beds occupied by patients with H1N1 varied. In Australia and New Zealand, it peaked at 19%,⁷ while in Mexico, many patients required mechanical ventilation outside the ICUs.⁶ To match the surge capacity with increasing ICU demands during a pandemic is a difficult task, since uncertainty exists for many of these parameters. The disease brought a surge of not only critically ill patients but also patients who required prolonged mechanical ventilation and ICU management. Hospitals should maximize the number of ICU beds by expanding ICUs and other areas with appropriate beds and monitors. Elective procedures should be minimized when resources are limited, and critical care capacity should be augmented.

Safe practices and safe respiratory equipment are needed to minimize aerosol generation when caring for patients with influenza. These measures include handwashing and wearing gloves and gowns; using N95 respirators, which reduce the transmission of epidemic respiratory viruses; staff training in personal protective equipment (PPE); minimizing the use of bag-mask ventilation and disconnection of the ventilator circuit; and avoiding the use of heated humidifiers on ventilators, Venturi masks, and nebulized medications.⁵²

When the number of critically ill patients far exceeds a hospital's traditional critical care capacity, modified standards of critical care to

provide limited but high-yield critical care interventions should be the goal to accommodate far more patients. Triage criteria should be objective, transparent, and ethical and applied justifiably and publicly disclosed. The ICU triage protocols for pandemics should only be triggered when ICU resources across a broad geographic area are or will be overwhelmed despite all reasonable efforts to extend resources or obtain additional resources.⁵³ The Sequential Organ Failure Assessment score, though not validated, has been proposed to determine qualification for ICU admission during mass critical care.

The major characteristics of 2009 H1N1 influenza A infection were the rapidly progressive lower respiratory tract disease leading to acute respiratory distress syndrome (ARDS) with refractory hypoxemia. A substantial number of H1N1 ICU patients required advanced ventilatory support (ranging from 1.7% to 11.9%) and rescue therapies including high levels of inspired oxygen and positive end-expiratory pressure (PEEP), inverse ratio ventilation, airway pressure release ventilation, neuromuscular blockade, inhaled nitric oxide, high-frequency oscillatory ventilation, extracorporeal membrane oxygenation (ECMO), volumetric diffusive respiration, and prone-positioning ventilation.^{46,49,51,54} ECMO was successful in managing refractory hypoxemia in these patients in two studies. The median durations of therapy and survival rates to ICU discharge were 10 days and 15 days—71% and 67%, respectively.^{55,56}

As of March 13, 2010, the CDC estimates of 2009 H1N1 influenza cases, hospitalizations, and deaths in the United States since April 2009 were 60 million cases, 270,000 hospitalizations, and 12,270 H1N1-related deaths, respectively.⁵⁷ The virus did not mutate during the pandemic to a more lethal form. Widespread resistance to oseltamivir did not develop. The WHO declared an end to the H1N1 pandemic on August 10, 2010. The H1N1 virus is expected to take on the behavior of a seasonal influenza virus and to circulate for some years.

Ebola Update

In late 2013, Ebola virus disease (EVD) became an international disaster of crisis proportion in West Africa, primarily in the countries of Liberia, Sierra Leone, and Guinea. This became the largest outbreak of EVD in history, greater than all previous epidemics combined, with a total number of 24,000 suspected cases and 9714 deaths, all in the aforementioned countries; importantly, there have only been 34 suspected cases and 15 deaths outside of those countries.⁵⁸⁻⁶⁰ This point cannot be overemphasized. Although the mortality of confirmed cases has been documented to be as high as 68% in the affected nations of West Africa, if patients are quickly recognized and given appropriate aggressive supportive care, the case fatality ratio drops dramatically. There are, to date, no specific pharmacotherapeutic interventions available to cure EVD; the dramatically decreased case fatality ratio noted in developed nations is related to strict enforcement of isolation, hygiene, and use of supportive care.

With regard to the scope of the issue, the CDC predicted that the number of confirmed EVD cases would double approximately every 20 days, with estimated cases ranging as high as 1.4 million. From a mass-casualty perspective, it rapidly became clear that the aforementioned nations of West Africa did not have adequate governmental infrastructure to create Ebola treatment units nor were they able to strictly implement the necessary public health infrastructure of hygiene and isolation. At that point, important nongovernment organizations (NGOs) such as Médecins Sans Frontières, Red Cross, WHO, and worldwide military support intervened to create the lacking infrastructure.^{61,62}

When patients with EVD first started appearing in the United States, it required some fundamental reevaluation of the role of the CDC in such events. Normally the agency is tasked with providing information and guidance to both healthcare facilities as well as state and local health departments, but given the rapid, complex, and international nature of this particular epidemic, the routine approach of having state health departments manage these situations with oversight by the CDC was not particularly effective. The president

created the role of “Ebola Response Coordinator” to help provide a coordinated federal oversight for the U.S. approach to this disease. In addition, the CDC created Ebola “SWAT teams” that were sent in real time to appropriate locations to ensure appropriate resource allocation to hospitals, and, if necessary, transfer patients with suspected EVD to properly equipped regional centers. For example, in New York State, the governor mandated that eight medical centers (five in New York City alone) were to be designated centers for patients with suspected EVD and that all hospitals needed to develop strategic plans for initial management of patients with suspected EVD.⁶³

Interestingly, despite the extremely low number of actual patients who were diagnosed with EVD in the United States, a challenging problem was media management; an initial lack of clear federal leadership rapidly led to confusion, fear, and misinformation being spread throughout the country. As an example, the PPE recommendations from the CDC were not aligned with the recommendations from the WHO. This left hospital officials confused about the best manner in which to protect their employees. Eventually, the recommended approach became more aggressive, and there was agreement between the CDC and WHO regarding PPE.^{60,64-69}

In conclusion, major important lessons were learned during the outbreak of EVD, many of which have clear-cut implications for future epidemics. First, it became clear that for many developing nations, the existing governmental infrastructure is inadequate to provide appropriate containment, public health infrastructure, and treatment facilities; early aggressive intervention by a combination of NGOs and militaries is required to quell the spread. Second, the standard existing paradigm of local and state health agencies providing adequate resources, information, and guidance to health facilities may not be adequate; a rapid top-down federalized approach may be required. Clearly, more resources must be allocated to our federal health agencies to prepare for such possible events in the future.

■ OTHER NATURAL DISASTERS

Tornadoes occur most commonly in the North American Midwest. Over 4115 deaths and 70,000 injuries have been ascribed to them during the years 1950 to 1994. They cause widespread destruction of community infrastructure. Injuries most commonly seen are complex contaminated soft-tissue injury (50%), fractures (30%), head injury (10%), and blunt trauma to the chest and abdomen (10%).^{70,71} Firestorms, wildfires, tsunamis, winter storms, and heat waves are other natural phenomena capable of creating mass injuries from thermal burns, airway injury, smoke inhalation, heat-related disorders, and hypothermia.⁷²⁻⁷⁵

■ MAN-MADE DISASTERS

Transportation Disasters

Transportation accidents can produce injuries and death similar to those seen in major natural disasters. Some of the largest civilian disasters in North America have been related to the transportation of HazMat.⁷⁶ Motor vehicle accidents, railway accidents, airplane crashes, and shipwrecks are some of the common transportation accidents. They cause a wide range of injuries including multiple trauma, fractures, burns, chemical injuries, hypothermia, dehydration, asphyxiation, and CO inhalation. The hazard risk to a healthcare facility increases with its proximity to a chemical plant or highway, and such factors should be considered in the emergency preparedness plan of a hospital.⁷⁷

Weapons of Mass Destruction

Weapons of mass destruction (WMD) are those nuclear, biological, chemical, incendiary, or conventional explosive agents that pose a potential threat to health, safety, food supply, property, or the environment. Since the terrorist attacks in September 2001 and intentional

release of anthrax spores in the United States, there is growing concern around the world about the possible threat of chemical, biological, or nuclear weapons being used against a civilian population. The incidence of use of WMD to cause death and injury is rare. However, biological and chemical weapons are relatively accessible, and WMD are thought to be available to most foreign states and terrorist groups. In response to a WMD incident, healthcare personnel will be called on to manage unprecedented numbers of casualties in an environment of panic, fear, and paranoia that accompanies terrorism. Because most attacks occur without warning, the local healthcare system will be the first and most critical interface for detection, notification, rapid diagnosis, and treatment. The best defense in reducing casualties will therefore rest on the ability of medical and public health personnel to recognize symptoms and provide rapid clinical and epidemiologic diagnosis of an event. This requires that healthcare providers be well informed of potential biological, chemical, and nuclear agents. They must have a heightened index of suspicion and be able to identify unusual disease patterns to determine whether WMD are the etiologic agents of illness. Physicians will need to practice appropriate surveillance and reporting and develop knowledge of mass decontamination, use of proper PPE, and safety protocols related to a biological, chemical, or radiologic event.⁷⁸⁻⁸⁰ Salient characteristics and brief management strategies of different WMD are discussed here.

Biological Weapons

Biological weapons can be either pathogens (disease-causing organisms such as viruses or bacteria) or toxins (poisons of biological origin). Compared with other WMD, biological weapons are characterized by ease of accessibility and dissemination, difficulty in detection because of their slow onset of action, and their ability to cause widespread panic through the fear of contagion. They can be spread through various means, including aerial bombs, aerosol sprays, explosives, and food or water contamination. Multiple factors including particle size of the agent, stability of the agent, wind speed, wind direction, and atmospheric conditions can alter the effectiveness of a delivery system. The CDC has classified biological weapons into three categories (Table 184-4) based on the ease of dissemination; ability to cause high mortality, public panic, and social disruption; and requirement for special action for public health preparedness.⁸¹ Category A agents are of

TABLE 184-4 Triage Classification

| GROUPS | COLOR | SYMBOL | TYPE OF INJURY |
|-------------------------------|--------|--------|--|
| Priority I (emergent) | Red | R | CRITICAL: likely to survive if simple* care given within minutes |
| Priority II (catastrophic) | Blue | B | CATASTROPHIC: unlikely to survive and/or extensive or complicated care needed within minutes |
| Priority III (urgent) | Yellow | Y | URGENT: likely to survive if simple† care given within hours |
| Priority IV (nonurgent) | Green | G | MINOR: likely to survive even if care delayed hours to days |
| Priority V (none) | Black | X | Dead |

*Simple: care that does not require unusual equipment or excessive use of time or personnel.

†Assigned THIRD priority (after YELLOWS) when there are so many casualties that if resources are used in vain to try to save BLUE cases, the YELLOWS will needlessly die.

From Auf Der Heide E. Disaster response: principles of preparation and coordination. St. Louis: Mosby; 1989.

Full-text online edition available at: http://sheltercentre.org/sites/default/files/CVMosby_DisasterResponsePrinciples.pdf.

particular concern because they can cause widespread disease through their ease of transmission, result in high mortality rates, cause panic and social disruption, and require special attention during public health preparedness. General features that should alert healthcare providers to the possibility of a bioterrorism-related outbreak include⁸² the following:

1. A rapidly increasing disease incidence (e.g., within hours or days) in a normally healthy population
2. An epidemic curve that rises and falls during a short period
3. An unusual increase in the number of people seeking care, especially with fever or respiratory and gastrointestinal complaints
4. An endemic disease rapidly emerging at an uncharacteristic time or in an unusual pattern
5. Lower attack rates among people who had been indoors, especially in areas with filtered air or closed ventilation systems, versus people who had been outdoors
6. Clusters of patients arriving from a single locale and large numbers of rapidly fatal cases
7. Any patient presenting with a disease that is relatively uncommon and has bioterrorism potential (e.g., pulmonary anthrax, tularemia, or plague)

The main steps involved in managing a bioterrorist attack are containment, notification, confirmation, and directed antibiotic treatment and prophylaxis. In the event of a suspected bioterrorist attack, the CDC has issued protocols for early notification of local and state public health department agencies.⁸³ The Association for Professionals in Infection Control and Epidemiology in cooperation with the CDC devised the "Bioterrorism Readiness Plan," with a template for healthcare facilities to serve as a reference document to facilitate preparation of bioterrorism readiness plans for healthcare facilities. This tool guides infection-control professionals and healthcare epidemiologists in the development of practical and realistic response plans for their institutions in the event of a bioterrorism attack.⁸⁴ The reader is referred to other documents for a review of bioterrorism and critical care,^{85,86} as well as other resources and websites (Box 184-1).

Chemical Weapons

Chemical incidents are accidental or intentional events that threaten or do expose responders and members of the public to a chemical hazard. Agents that have been commonly used as chemical weapons are also used in industrial processes. Most industrial incidents occur at an interface between transport, storage, processing, use, or disposal of hazardous chemicals, where these systems are more vulnerable to failure, error, or manipulation. The catastrophic effect of these agents has been utilized several times in the past for military purposes, and with the proliferation of these weapons, civilian populations are now faced with a significant threat.⁸⁷ Typically, chemical warfare agents are classified into the following categories⁸⁸:

Nerve agents (e.g., tabun, sarin, VX, and soman) are organophosphates that inhibit an enzyme, anticholinesterase, resulting in the overstimulation of both muscarinic and nicotinic receptors. Muscarinic symptoms include lacrimation, bronchorrhea, bronchospasm, miosis, salivation, rhinorrhea, vomiting, and diarrhea. Nicotinic receptor stimulation produces muscle fasciculations, flaccid paralysis, tachycardia, and hypertension. They can also produce central nervous system effects (i.e., seizures and coma). Death is usually from respiratory failure. They are extremely toxic and have a rapid effect. Sarin presents as a vapor threat, and the onset of symptoms is within seconds, with a peak effect in 5 minutes. Exposed victims who are asymptomatic after 1 hour are unlikely to be contaminated. VX represents a liquid exposure, with as little as a drop being lethal. The onset to action and death is less than 30 minutes. The cardinal rule in decontaminating patients is to remove and dispose of all articles of clothing. Therapy is directed toward the predominating symptoms. Atropine is used for the relief of muscarinic symptoms, pralidoxime chloride (2-PAM) is used for nicotinic effects, and benzodiazepines are used for the central nervous system manifestations. Most of the care is supportive and includes mechanical ventilation for respiratory failure and treatment of arrhythmias.⁸⁹

Vesicants (e.g., mustard gas and lewisite) cause wounds on the skin and mucosal surfaces. They are capable of causing second-degree burns of the skin within 4 to 8 hours. Airway injury and edema can be severe and are dose dependent. Of concern to the ICU physician is the need for correcting fluid losses and maintaining the airway.

Pulmonary agents (e.g., chlorine gas and phosgene gas) mainly affect the respiratory system, inducing inflammation of the airway and the lung and leading to ARDS and death. Treatment is mainly supportive.

Cyanides bind to cytochromes in the mitochondria and inhibit cellular oxygen use. In smaller doses they cause tachypnea, headache, dizziness, anxiety, and vomiting. With higher doses, seizures, respiratory arrest, and cardiac arrest occur. They are highly toxic, and sufficient levels can cause death within 5 minutes of inhalation. They are most commonly inhaled but can also be absorbed through the skin. Care is primarily supportive with supplemental oxygen. Specific therapy is with amyl nitrates, sodium nitrite, and sodium thiosulfate.

Unlike biological weapons, disease secondary to release of chemical agents is likely to be more obvious, rapid in onset, and homogeneous. However, they pose serious problems for emergency care providers because of their potential to cause a large number of casualties rapidly and their potential for secondary contamination. Any emergency medical or public health response to a major incident involving a chemical warfare agent will require coordination among local, state, and federal organizations. First responders should be aware of access to specialized local and federal response teams, basic triage, and demarcation of the contaminated area, use of handheld devices for agent detection and identification, use of PPE, and knowledge of appropriate medical treatment and antidotes.

Nuclear Weapons and Radiation Accidents

A variety of terrorist applications of radiation exist that could produce varying degrees of damage to public infrastructure and operations, human casualties and illnesses, and most important, fear.

Radiation devices include radionuclides from the healthcare industries (e.g., brachytherapy and radiation oncology sources). The consequences of the exposure are dose and source dependent.

Radionuclide dispersal devices are also known as *dirty bombs*. These have limited nuclear yield but can contaminate a wide area.

Improvised nuclear devices are made of uranium or plutonium constructed by a nongovernmental source and limited by the critical mass of nuclear material. They yield less destructive power than a conventional nuclear warhead but are still capable of contamination effects.

Tactical and strategic nuclear weapons are those that are created by governments and vary in yields from 0.5 kiloton to greater than 1 megaton. Their destructive capacities are enormous, and they contaminate a vast perimeter of space depending on the yield.

Approximately 50% of the energy released from a nuclear bomb is due to the blast and shock waves, giving a majority of the survivors blast-related injuries and creating extensive infrastructure damage. About 35% of the energy released is thermal radiation (in orders of tens of millions of degrees), giving rise to high-degree skin burns. Depending on the size of the device and the altitude of detonation, an electromagnetic pulse is generated with the explosion. This is capable of disrupting all electrical equipment within 20 km to several hundreds of kilometers.⁹⁰ The radiation-related energy released gives rise to external contamination, systemic irradiation, and internal contamination-related illness. Immediate ionizing radiation consists of gamma, beta, neutron, and a small amount of alpha radiation. Residual radiation occurs in the forms of induced radiation and fallout. Induced radiation occurs because of neutron-induced gamma activity of the immediate soil, silicon, manganese, aluminum, zinc, copper, and sodium. The half-lives of the various substances are a few minutes to 15 hours. *Fallout* is the fusion of various radionuclides generated in the fission reaction with condensation, producing a snowflake-like debris that falls to earth. Fallout is a potential form of delayed radiation exposure and can cause internal contamination.⁹⁰

Surviving hospitals and staff near an impact area should serve as a triage center and transport victims to unaffected centers elsewhere through the notification of the National Disaster Medical System Hospital Activation System.⁹¹ Other agencies that have to be notified include the Federal Bureau of Investigation, Nuclear Regulatory Commission, Department of Energy, and Department of Defense. Large-scale decontamination should be managed outside the hospital area as far as is possible, but plans for indoor decontamination should also be in place. A radiation emergency area (both in and out of the hospital) should be designated, with checkpoints nearing the cold zone. Management plans for the safe disposal of human waste and bodies should be in place so as not to increase the exposure risk. Triage of patients should be done on the basis of doing the greatest good for the greatest number. On the basis of predictive models, isolated irradiation, burns, and blast-related injuries would constitute 40% of injuries. Combined injuries would account for the rest. Attending to trauma victims should take precedence over all other medical issues, because a given patient is not likely to succumb immediately from radiation injury.

Patient care should begin with the use of universal precautions and PPE.⁹⁰ Dosimetry readings of the area may help during triage, defining those with systemic irradiation injury (possibly received >450 rad exposure). In determining patient viability, three parameters are of the most use: time of onset of vomiting, decrease in the absolute lymphocyte count over a 24-hour period, and presence of conventional trauma burns.⁹² Victims who are not viable or who have lethal doses of radiation exposure are likely to benefit from supportive/palliative care.

Hazardous Materials Disasters

HazMat are substances potentially toxic to the environment or living organisms. Full-scale disasters from HazMat are relatively rare, but isolated incidents are among the most common in the community and are not limited to chemicals but can include various biological and radiologic materials. Knowledge of the types of industries present in the community would be helpful in developing a potential plan to deal with likely HazMat situations. Management of a HazMat situation requires attention to several key points: identification of the offending agent, appropriate PPE of responders, prompt containment of the agent, demarcating areas for decontamination (including removal and disposal of clothes and waste from the decontamination), and resuscitation of victims. Injuries secondary to release of HazMat can present as chemical burns, inhalational injury, and a variety of systemic injuries.^{93,94}

Armed Conflict

Armed conflict continues to be the most preventable and most destructive of man-made disasters in terms of human physical and emotional suffering, economic loss, and environmental destruction. Specific healthcare issues during these conflicts that are relevant to the intensivist include trauma from blast injuries, projectiles, and crush-related injuries; communicable diseases due to the breakdown of public infrastructure and mass displacement of populations; and burns and radiation-related injury.

MEDICAL DISASTER SYNDROMES

Disaster situations present with many unique medical syndromes that require specific therapy. Treatment of these entities is often difficult because of a large volume of patients, lack of qualified medical personnel on-site, and inadequate supplies and equipment. It is important to emphasize that initial recognition of the medical syndromes and appropriate intervention are critical to minimizing morbidity and mortality. Appropriate triage, knowledge of field management of each syndrome, flexibility to adapt to each situation, ability to ignore natural differences among different specialties, and recognition of limits of medical care that can be provided in overwhelming situations are key to a good disaster medical response. In the following paragraphs, we discuss commonly encountered medical syndromes in a disaster situation.

Blast Injuries

Bombs contain an array of compounds such as nitroglycerin, trinitrotoluene, and others that are encased in a metal or plastic case. Decomposition of the solid or liquid compound into gas leads to massive dissipation of energy and pressure that creates a blast wave (shock wave). This destructive effect can be increased by the presence of nuts, nails, and bolts in the casing. Water transmits blast waves more efficiently than air, with the greatest impact being on structures that are the deepest.⁹⁵ There are four types of blast injuries:

1. *Primary blast injury* is caused solely by the blast wave and almost always affects air-filled structures such as the lung, ear, and gastrointestinal tract. The presence of tympanic membrane rupture may indicate exposure to a high-pressure wave and is thought to correlate with more severe organ injury.
2. *Secondary blast injury* is caused by the rapid acceleration of small fragments caused by the blast injury.
3. *Tertiary blast injury* is a feature of high-energy explosions. They result from the collision of the flying victim against a hard surface.
4. *Miscellaneous blast-related injuries* encompass all other injuries caused by explosions. They include flash burns, inhalation injuries, and blunt trauma.

The most common injuries associated with fatality in blast incidents include subarachnoid hemorrhage (66%), fracture of the skull (51%), lung contusion (47%), tympanic membrane rupture (45%), and liver laceration (34%). Unfortunately, the extent of the blast injury cannot be assessed during the course of rapid triage examinations. In the absence of overt trauma, a focused physical examination should include examination for ruptured tympanic membrane, hypopharyngeal contusions, hemoptysis, and auscultation for wheezing. The presence of a ruptured tympanic membrane is almost always an indicator that the patient has been exposed to a blast wave powerful enough to cause serious damage. The thorax is frequently involved in a blast injury, manifesting with wheezing, hemoptysis, pneumothorax, hemothorax, and air embolism. Patients may have myocardial contusion as well. The presentation of serious pulmonary injury may be delayed. Pulmonary barotrauma is the most common fatal primary blast injury. Patients with nonpenetrating lung injury will likely have hypoxia requiring support ranging from oxygen therapy to mechanical ventilation. This may result from pulmonary contusion, systemic air embolism, and disseminated intravascular coagulation. Acute gas

embolism, a form of pulmonary barotrauma, is also associated with blast injuries. Air emboli most commonly occlude blood vessels in the brain or spinal cord, resulting in neurologic symptoms that must be differentiated from the direct effects of trauma. Patients thought to have gas embolism require decompression treatment. Administering 100% oxygen by tight-fitting face mask and left lateral recumbent position may help. Definitive treatment is with the use of hyperbaric oxygen. Patients with blast injury of the lung are likely to present with abdominal injuries that are usually more delayed. These include delayed bowel perforation and liver lacerations. The former may warrant exploratory laparotomy.⁹⁶⁻⁹⁹

Blast victims receiving general anesthesia have an increased mortality rate; other forms of local and spinal anesthesia are preferred, and general anesthesia should be deferred if possible for 24 to 48 hours. Intensivists should be aware of the increased need for resuscitation equipment, ventilators, and movement in and out of the operating room during such situations.

All patients with significant burns, suspected air embolism, radiation or white phosphorus contamination, abdominal signs of contusion/hematoma, or clinical evidence of pulmonary contusion or pneumothorax should be admitted to the hospital. Patients with tympanic membrane rupture and suspected pneumothorax should get some form of chest imaging, and a significant observation period may be warranted. Other investigations must be judiciously ordered, keeping in mind the limited availability of resources in a mass-casualty incident. Screening urinalysis for presence of hematuria, tests for CO poisoning (explosion in a closed space or associated with fire) and cyanide toxicity (due to combustion of plastics), and assessment of acid-base status may be indicated. Using abdominal computed tomography to rule out intestinal hematomas should be dictated by clinical signs and symptoms. Pregnant patients with blast injuries warrant special consideration, and appropriate consultation is necessary to rule out blast injury to the fetus.⁹⁷ Supplemental oxygen, maintaining spontaneous respiration, and low PEEP (if mechanical ventilation is required) are guiding principles. Routine corticosteroids and antibiotics are not warranted.

Exposure to white phosphorus explosives (e.g., in hand grenades) deserves special mention. Using a Wood's light in a darkened resuscitation suite or operating room may help identify white phosphorus light particles in the wound. White phosphorus injury can cause lung injury through irritation, as well as severe hypokalemia and hyperphosphatemia with cardiac arrhythmias and death. External burns should be lavaged with 1% copper sulfate solution. This forms a blue-black cupric phosphide coating and prevents combustion so that the particles can safely be removed.¹⁰⁰

Crush Injury Syndrome

Crush injury syndrome refers to systemic manifestations of extensive muscle damage caused by entrapment of victims under collapsed buildings or debris. Reported incidence depends on the type of disaster, ranging from 2% to 40%. Metabolic alterations from the release of muscle constituents into the circulation include myoglobinemia leading to acute renal failure, hyperkalemia, hyperphosphatemia, and disseminated intravascular coagulation. Muscle damage that occurs is due to not only direct crush injury but also vascular injury and insufficiency leading to altered compartment pressures and reperfusion injury. Inelastic fascial sheaths encase skeletal muscles in the forearm and lower leg and are particularly vulnerable to dramatic increases in compartment pressures, resulting in compartment syndrome. An intracompartmental pressure greater than 40 mm Hg lasting longer than 8 hours defines this syndrome. Pressures as high as 240 mm Hg can be seen with crush injuries. Compartment syndromes are seen with limb fractures, use of military antishock trousers, pneumatic splints, vascular injuries, and crush injuries. The affected limb may present with severe pain associated with passive stretch or extension, flaccid paralysis, and sensory loss. Capillary refill and peripheral pulses are usually present unless the compartmental pressure equals the diastolic pressure. Diagnosis requires a high degree of clinical suspicion

and entails prompt bedside measurement of compartmental pressures. A simple and easy method that can be performed in the hospital or field hospital is using an 18-gauge needle attached to a mercury manometer. In an ICU, pressure transducers used to measure central venous pressures can be attached to the 18-gauge needle to obtain the same information.¹⁰¹

Resuscitation of patients with crush injury (any victim crushed or immobilized for more than 4 hours) should begin in the field. After adequate intravenous access is achieved, isotonic fluid replacement with normal saline (rate of 1-1.5 L/h) should begin even before extrication of the crushed limb. If fluid therapy is delayed, the incidence of renal failure increases to 50%; delays of 12 hours are associated with a 100% incidence. Occurrence of renal failure is associated with a mortality rate of 20% to 40%. Urinary alkalization with sodium bicarbonate and mannitol or acetazolamide administration is used to maintain urine pH above 7.5. Although this is widely used, there are no prospective randomized controlled trials to support it. Dialysis may be indicated if aggressive fluid resuscitation fails, and this may create a huge demand for dialysis machines in disaster situations. Peritoneal dialysis if the abdomen is intact and continuous arteriovenous hemofiltration may be other useful options. However, the latter option is complicated by hemorrhage problems related to the use of heparin and immobilization. Life-threatening infections are common and may be increased in the presence of a fasciotomy. In unsalvageable limbs, it may be advisable to perform on-field amputations to avoid the systemic effects of a crush injury syndrome. For this purpose, ketamine is the anesthetic and analgesic of choice because of its safety profile in the field.¹⁰¹

Particulate Health Problems

Many disasters result in the release of copious particulate matter, causing a wide spectrum of respiratory illnesses including cough, wheezing, smoke inhalation injury, reactive airways disease, and ARDS. Volcanic eruptions with associated pyroclastic flows and ash fall are some of the most devastating producers of particulate matter. Mortality arises from suffocation by ash in the upper airways, ARDS, and inhalation burns. The massive building collapse and fires associated with the 2001 World Trade Center terrorist attack caused significant pulmonary complaints among rescue personnel.¹⁰²

Smoke inhalation injury resulting from exposure to noxious products of combustion in fires may account for as many as 75% of fire-related deaths in the United States. The three primary mechanisms that lead to injury in smoke inhalation are thermal damage, asphyxiation, and pulmonary irritation. Combustion uses oxygen in the airways and causes a decrease in fraction of inspired oxygen, leading to hypoxemia. Increased CO levels decrease the oxygen-carrying capacity of the blood and cause myocardial depression. Combustion of plastics, polyurethane, wool, silk, nylon, rubber, and paper products can lead to the production of cyanide gas, resulting in anaerobic metabolism and decreased oxygen consumption. Rarely, we may also find methemoglobinemia, which reduces oxygen-carrying capacity.¹⁰³ Mortality rate with smoke inhalation alone is about 10% but increases to about 77% in the presence of major burns or respiratory failure. Early deaths are mostly caused by airway compromise or metabolic poisoning. Laboratory workup should include co-oximetry; CO, methemoglobin, and cyanide levels (if there is discordance in measured saturation and pulse oximetry readings); blood lactate levels (a level >10 mmol/L that is refractory to restoration of adequate ventilation, oxygenation, and perfusion is considered a surrogate marker of cyanide toxicity) on blood gases; and a calculated alveolar-arterial pressure gradient. Initial blood gas measurements and chest radiograph may be normal. Carboxyhemoglobin level obtained in the emergency department does not correlate with tissue hypoxia or long-term neurologic sequelae; ideally, a carboxyhemoglobin level at the scene would be most valuable.

Serial bronchoscopy is indicated in the first 18 to 24 hours to assess airway edema and sloughing. Early bronchoscopy can be of diagnostic and therapeutic value, particularly when lobar atelectasis is

present. High-flow humidified oxygen is critical to reverse or prevent hypoxemia. About 50% of patients with an inhalation injury require tracheal intubation, and this increases in patients who have burn injuries. The need for intubation is determined by the need to maintain airway patency and pulmonary toilet and to provide positive-pressure ventilation. Positive-pressure ventilation with PEEP increases short-term survival and is associated with decreased tracheobronchial cast formation. Cyanide toxicity (levels >0.1 mg/L) should be promptly treated using a cyanide antidote kit. Recommendations for the use of hyperbaric oxygen in the setting of CO poisoning include CO levels greater than 25% to 30%, neurologic compromise, metabolic acidosis, or electrocardiographic evidence of myocardial ischemia, infarction, or dysrhythmias. Hyperbaric oxygen has been used in cyanide toxicity but has not been proven effective. The role of corticosteroids is controversial, and they can be detrimental if given in the presence of cutaneous burns. Empirically administered antibiotics are also in dispute. Common pitfalls in the initial management of smoke inhalation are using initial PaO_2 to predict adequacy of oxygenation, placing small-diameter nasotracheal tubes, intubating without applying PEEP, and restricting fluids for concomitant inhalation and burn injury.^{103,104} General measures that could be employed in a field setting include simple airway protection by clearing any particulate matter in the airway, supplemental oxygen, and nebulizer treatment if available. Patients with preexisting asthma and emphysema should be observed for exacerbations.

Acute Radiation Syndrome

Ionizing radiation can be either charged or uncharged particles (photons). Beta particles are capable of penetrating a few centimeters of tissue. Gamma rays and x-rays are capable of penetrating through tissue and concrete. Gamma, x-ray, and beta radiations are considered low linear energy transfer radiation. Alpha particles have no penetrating power past the keratinized layer of skin, but they take on clinical significance if they are internalized by ingestion or inhalation. Neutron emission (e.g., from nuclear reactors, nuclear devices, and industrial moisture detectors) is a highly potent radiation that penetrates deep and creates denser ionization trails. Alpha and neutron emissions are considered high linear energy transfer radiation and have more biological effects than low linear energy transfer radiation by a factor of up to 20. When the process of ionization occurs in living tissue, it denatures cellular DNA. This leads to impaired mitosis and subsequent organ failure. Large doses of radiation are considered to cause more biological destruction than fractionated doses. Systemic radiation illness and lethality from it can result from as little as 450 rad. Precise measurements of the amount of radiation after a nuclear accident will be delayed. Hospital gamma cameras are an invaluable resource for helping determine the exposure in an individual. Higher systemic doses are suggested by shorter onset of prodromal symptoms such as nausea, vomiting, and diarrhea. Serial absolute lymphocyte counts will screen those patients who have psychogenic vomiting. Acute radiation syndrome has four distinct phases.^{79,90,92}

1. *Prodromal phase*, characterized by nausea, vomiting, and diarrhea. Other symptoms of eye burning, abdominal pain, and fever can also occur with higher doses. This phase may last from 0 to 2 days, depending on the dose received.
2. *Latent phase*, in which the patient will have a period of relative well-being because of subsidence of the inflammation. However, ultimately the damaged cells will not be able to repair or regenerate. This may last for 2 to 3 weeks.
3. *Manifest phase*, in which the cellular deficits of various organs affected will become apparent. Mature cells of the skin slough off, revealing an atrophic dermis. Endothelial cells are not replaced, leading to vascular permeability. Mucosal linings slough, causing mucositis and diarrhea. Hematopoietic progenitor cells fail to produce cell lines, leading to anemia, thrombocytopenia, and neutropenia. Fibrosis of organ beds develops. This may last for up to 3 weeks.

4. *Recovery phase/death*, in which some stem cells may proliferate and lead to slow recovery, or there will be symptoms of progressive organ failure leading to death.

For radiation syndrome to occur, radiation must be of the penetrating type in a sufficiently large dose (>0.7 Gy), must be external, and must occur within a short time. The disease complex has three syndromes: bone marrow, gastrointestinal, and cardiovascular/central nervous system. Serial absolute lymphocyte counts should be measured immediately on suspicion of exposure (every 3 hours), because lymphocytes are among the most radiosensitive cells and reach nadir within 2 days, platelets reach nadir in 15 to 30 days, and neutrophils at about 30 days. Patients are immunocompromised and susceptible to infections, including septic shock. Gastrointestinal syndrome leads to mucosal sloughing, decreased nutrient absorption, and translocation of bacteria and endotoxin. Veno-occlusive disease may also develop if the dose is large enough. Cardiovascular and central nervous system disease develops with doses greater than 5000 rad, and death can occur in as little as 3 days from myocarditis, capillary leak, pulmonary edema, and brain edema. Pneumonitis and subsequent fibrosis can lead to respiratory failure and the need for ventilator support. Treatment of Acute Radiation Syndrome (ARS) is supportive. If internal contamination is thought to have occurred, enhancement of excretion and specific antidote therapy are warranted. For inhalational contamination, bronchoalveolar lavage may be necessary, and for ingestion, gastric lavage and purgative management are warranted. Plutonium and transuranic elements can be treated with chelating agents such as calcium or zinc diethylenetriamine pentaacetic acid. Radiocesium can be treated with Prussian blue, which helps enhance excretion in feces. Radioiodine exposure can be treated with potassium iodide. Uranium excretion can be enhanced by the alkalization of urine and with potassium supplementation.

Psychological Trauma

The psychological component in a traumatic event is often overlooked, with the major focus usually being on physical health issues. Studies evaluating the emotional impact from disasters indicate that a majority of victims, first responders, and mortuary volunteers will suffer some form of psychological trauma. Intensivists should be aware that behavioral changes may be due not only to the catastrophic insult but also organic causes such as head injury, inability to take predisaster psychiatric medications, and toxin or chemical exposure. Groups at risk, such as children, adolescents, and victims who have been exposed to traumatic stressors of bereavement, witnessing death, and situations evoking guilt, fear, or anger, should receive prompt psychiatric and posttraumatic counseling. Interventions, such as debriefing, eye movement desensitization and reprocessing, and critical incident stress management, may help minimize emotional suffering and morbidity.¹⁰⁵

Other Syndromes

Burns, blunt trauma, intraabdominal injury, head injuries, penetrating trauma, and hypothermia are some of the other disaster syndromes encountered in the field. Specific discussion of these entities is beyond the scope of this chapter; please see other reviews.⁵

DISASTER PREPAREDNESS

For intensivists to be able to deal with a disaster, it is paramount that they be a part of the disaster-planning effort. Disaster planning includes development of action programs to minimize loss of life and damage during a disaster, provide the greatest good for the greatest number of people, train healthcare personnel and civilians, coordinate response efforts, maintain adequate supplies of equipment and personnel, and rehabilitate the community after the disaster. Knowledge of potential disasters to which the community is prone should be an integral part of the planning process. Having an understanding of what the resources and capabilities are of the community, hospital, and its ICU on a

continual basis and provision for modular expandability are vital for any successful emergency response. The mere existence of a disaster plan does not ensure that the hospital system is actually prepared.¹⁰⁶ The following paragraphs elucidate some of the common issues and misconceptions related to disasters and common principles useful in designing a disaster plan. Subsequently, a pragmatic view is presented of the role of the ICU physician in a disaster situation.

Common Issues and Misconceptions in Disaster Planning

Typically, the hospital nearest to the disaster site will receive the bulk of the casualties. It is thus important to conduct a careful survey of a disaster plan's jurisdiction to identify potential sites (i.e., industries, nuclear reactors, and highways) and likely types of hazardous events that could occur in the area. Hospitals in the nearby area receive few disaster victims, and an average have at least 20% of their beds vacant. Disaster plans would thus need to include transfer agreements between hospitals and nearby ICUs to meet bed shortages by activating the National Disaster Medical System Hospital Activation System.^{91,106,107}

Very few casualties actually require hospital admission. A study of 29 mass-casualty incidents found that less than 10% of casualties required overnight admission under usual criteria (even though more were admitted because they were involved in the disaster rather than because of severity of their condition). Large numbers of casualties with minor conditions will appear at the nearest hospitals, often on foot or in private vehicles, police cars, buses, taxis, and other nonambulance forms of transport. Field triage stations are often bypassed, and this in turn causes enormous strain on the emergency department services.¹⁰⁸

Most of the logistical problems faced in disaster situations are not caused by shortages of medical resources but rather from failure to coordinate their distribution.¹⁰⁶ Inexperienced volunteers may not be familiar with the triage system or principles of personal safety, and massive numbers of volunteers can present serious administrative challenges. This results in disorganization and inefficiency.⁹³ Technical hazard sheets designed by the WHO for most disasters also suggest that medical personnel, blood donors, and blood products should not be sent empirically to a disaster site.¹⁰⁹

Principles in Disaster Planning

Existing Preparedness Requirements

In developing disaster plans, hospitals must take into account the broad national and local requirements imposed by various governmental agencies. Common agencies involved in this process include the Centers for Medicare and Medicaid Services (CMS) as well as The Joint Commission (TJC). The CMS's conditions for emergency preparedness and services establish minimum requirements for hospitals that participate in Medicare or Medicaid programs. Similarly, TJC standards apply to a full range of hospitals and are focused on four areas: (1) emergency preparedness management plan (Standard EC 4.1), (2) security management plan (Standard EC 2.1), (3) HazMat and waste management plan (Standard EC 3.1), and (4) emergency preparedness drills (Standard EC 4.2). Readers are referred to TJC website for the most up-to-date standards.¹¹⁰

Hazard Vulnerability Analysis

This is the first step of any disaster plan, with the main aim of identifying potential hazardous events and situations that can occur in or around the healthcare facility. This process of evaluating and predicting hazard risk is not restricted to geographic events but extends to institution-specific variables such as utility failures, local threats of gang-related activity, and presence of a local high-risk industry such as a chemical or nuclear power plant. TJC requires a formal documented HVA that is integrated with the emergency management plan, setting priorities among potential emergencies and also defining the hospital's role in the local community-wide emergency plan.¹¹⁰

Incident Command System

The Incident Command System (ICS) is designed to provide the basic architecture of an emergency management response. Major barriers to medical response arise from the lack of coordination among various public and healthcare agencies and from the lack of operational integration of various medical specialties. The ICS incorporates all these agencies and ensures a cooperative and effective response to a crisis. The concept of ICS resulted from the analysis of the devastating wildfires in Southern California in 1970 and has since been modified and successfully adapted to different disaster situations related to healthcare facilities.⁹⁶⁻⁹⁸ The ICS specifies a common terminology and a command structure with five functional sections:

1. **Command:** Unified command staff responsible for overall management of the incident
2. **Operations:** Performs the actual response work under the directives of the command center
3. **Planning:** Gathers relevant information and develops response strategies as the situation progresses
4. **Logistics:** Responsible for facility-wide supplies, equipment, personnel, and services. It also provides for basic services to personnel of the command center
5. **Finance:** Authorizes expenditures, maintains records, and provides documentation of the incident

There is a designated person who will have the authority to declare an emergency. All personnel involved in the command system should be aware of the exact predetermined location of the command center. The plan should also provide protocols that will guide notification and the sequence of mobilization of these personnel in a disaster situation. The command system must also have independent telephone lines to ensure uninterrupted communication with the external world in a disaster situation. Once initiated, the ICS has a built-in chain of command that would be responsible for triage of patients and allocation of personnel and resources.¹¹¹

Triage

Appropriate triage is a vital function during an emergency management response. This is a dynamic process that is not necessarily confined to the disaster site or the emergency department but is rather carried through several levels of the medical response pathway of a disaster response. Modern triage is based on the likelihood of survival in relation to the resources available at the time of the decision.¹¹² Problems often encountered in the triage process include the following¹¹³:

1. Lack of medical direction at the scene. Making triage decisions in a chaotic situation requires skill and experience and can often initially seem confusing and unmanageable. Lessons from the first Persian Gulf War showed that on-field triage was correct only 70% of the time. It is necessary to entrust experienced physicians with this job and to have simple and clear guidelines for the decision-making process. In addition to emergency physicians and trauma surgeons, critical care physicians bring with them the expertise to deal with complex and time-bound situations and are thus well suited to head a triage team.
2. Lack of interorganizational planning. Dynamic management of the triage process requires interorganizational coordination and flow of information. Up-to-date assessment of medical resources and personnel should be communicated from the command center to the triage site, and similar communication should occur from the scene to the command center. This will allow for rational and appropriate triage based on the availability of resources.
3. Transport of victims from the site by nonambulance vehicles to nearby hospitals.
4. There is no universally accepted form of triage. A recommended system uses a color-coded system to sort out disaster victims.¹¹²

Major Utilities, Supplies, and Equipment

Disaster plans and drills should factor in the possibility of internal and external power outages and related disruptions (ventilator and

monitoring device failures, communication failures including breakdown of cellular phones, and elevator failures) and water and gas supply shortages. The plan should have an up-to-date inventory of all supplies and capabilities of the facility. The numbers of ventilators in use and their absolute capacity, inventory of various ICU supplies, and vendor lists should be readily available if there is sudden demand for supplies. The disaster plan should allow for at least 2 days' worth of supplies. Regular drills will help identify various bottlenecks and provide knowledge of the absolute capacity of devices, equipment, and services in a disaster situation. Plans to evacuate critically ill patients to nearby hospitals in the event of failure of backup systems should be addressed. Since the anthrax attacks and the resulting strain on antibiotic supplies in 2001, more attention has been paid to the national repository of lifesaving pharmaceuticals and medical supplies called the *National Pharmaceutical Stockpile Program*. This response is a component of the CDC's larger Bioterrorism Preparedness and Response Initiative and is composed of a stockpile of pharmaceuticals, vaccines, medical supplies, and equipment to augment local and state resources in a disaster situation. After a federal decision to deploy, a "push package" will arrive by ground or air in 12 hours or less at any location in the United States. A CDC team accompanying the push package will then define shipments in the second phase.¹¹⁴

Security and Casualty Reception

Security is a major concern during natural or man-made disasters. Desire to seek immediate medical evaluation, panic, and curiosity are factors that place the healthcare facility and its personnel under enormous strain. Internal and external traffic control, protection of personnel involved in the response effort, and strict enforcement of staging and triage areas are key security-related issues. Law enforcement plays a more critical role during terrorist attacks or bioterrorism, and failure to maintain order will lead to rapid overwhelming of the facility's resources and a disorganized medical response. Because most victims will arrive at the hospital by foot or by personal vehicles, provision must be made for a predetermined staging area with adequate mass decontamination facilities and respiratory protective equipment.^{110,115}

ISSUES UNIQUE TO THE INTENSIVE CARE UNIT

The responsibility of caring for the most serious salvageable casualties in natural and man-made disasters will ultimately involve the critical care physician. As opposed to the overwhelming shortage of resources, lack of coordination among various agencies and specialties has been often cited as the main contributing factor to an ineffective emergency medical response. This response therefore requires the cooperation of not just physicians but also among prehospital medical personnel, nurses, and ancillary services such as radiology and laboratory services.⁵³

Possible roles for the intensivist as part of a disaster management planning team include the following:

1. Clear role definition and understanding of the overall organization of the emergency response plan
2. Knowledge of the usual limit, surge capacity, and absolute limit of ICU resources
3. Construction of appropriate staffing models

CRITICAL CARE IN UNCONVENTIONAL SITUATIONS

Mobile ICU Teams

There have been numerous examples in the medical literature describing extended critical care through mobile ICU teams. Using mobile

ICU teams has not been restricted to disaster settings but has also been used throughout the world during peacetime. Various factors that have to be considered in forming ICU teams are discussed next.

Personnel

On the basis of the anticipated needs of the disaster, appropriate specialists and ancillary personnel are chosen. Given the complexity and inherent unpredictability of staffing for disaster management, a flexible and adaptable approach must be taken to staffing such events.¹¹⁶

Training

Adequate predeparture training is essential for a coordinated and effective response. In addition, interaction and on-site training ensure effective functioning of a foreign medical unit and allow for the smooth transition of care to local physicians when the foreign team departs.⁹⁶

Casualty Assessment

Studies from the past and also the experience of the Israeli defense forces in providing care to earthquake victims in Turkey showed that the effectiveness of mobile ICU teams was limited by time. It may take 3 days to mobilize such an effort, and crucial time is lost before delivery of care. Efforts must thus be made to epidemiologically assess the efficacy of such teams. They should include review of the overall effort and adequacy of the ICU teams, outcome of victims, operational costs, and analysis of the structure and process of the ICU in the field.¹¹⁶

CRITICAL CARE TRANSPORT

Common principles involved in the safe transport of patients include the following¹¹⁶:

1. Rapid assessment of the severity of injuries, recognition of the need for transport, and anticipation of problems during transport
2. Safe movement of patients in and out of vehicles, continuous monitoring of vital signs, and recognition and treatment of problems encountered during transport
3. Documentation of the events during transport and provision of a detailed report to the admitting personnel

Types of Transport

Ground Transport

Ground ambulances have the advantage of rapid deployment, high mobility, and lower cost. However, patients and equipment are subject to significant deceleration and vibration forces. Equipment may vary depending on the size of the ambulance and usually includes blood pressure and electrocardiograph monitors, pulse oximeters, ventilators, and in some cases, modern support devices such as intraaortic balloon pumps.

Air Transport

It is beyond the scope of this chapter to provide a full detailed discussion of fixed-wing or rotary aeromedical transport, but it may be necessary during certain disasters to extricate victims via air.¹¹⁶

CONCLUSION

Understanding the characteristics of different disasters, developing an interdisciplinary approach to hazard mitigation, and knowledge of related clinical syndromes are key to an effective medical disaster response. To ensure an integrated and effective response to future disasters, it is necessary for critical care physicians to understand the fundamental principles in disaster medicine and participate in the disaster-planning process.

KEY POINTS

1. Disaster medicine is a unique specialty that has evolved over the past few years. It shares a common ideal with public health: "greatest good for the greatest number." Critical care medicine forms an indispensable part of this science because intensive care physicians not only care for the sickest of the salvageable patients in any hospital but also bring with them their clinical expertise in triage, resuscitation, and help in providing care outside the domains of the unit through mobile ICU teams.
2. Clear, common, and concise definitions are important in effective communication and evoking appropriate responses to disaster situations. The concept of functional impact of a disaster on the healthcare system is paramount while classifying disasters.
3. It is important to understand the common effects of different natural and man-made disasters to predict their impact on the healthcare system. Even though man-made disasters such as terrorist attacks have gained attention, the numbers of geophysical disasters such as earthquakes, floods, and hurricanes have remained fairly constant and place the greatest burden on the healthcare system.
4. Disaster situations produce many unique medical syndromes that require specific therapy. Knowledge and immediate recognition of different medical syndromes with appropriate interventions is critical to minimizing morbidity and mortality.
5. Disaster planning includes developing action programs to minimize loss of life and damage during a disaster, training healthcare personnel and civilians, coordinating response efforts, maintaining adequate supplies of equipment and personnel, and rehabilitating the community after the disaster. Knowledge of potential man-made and natural disasters to which the community is prone should be an integral part of the planning process. Common principles involved in the creation of an emergency response plan should be followed and applied from an ICU perspective.
6. With their natural role of caring for critically ill patients, intensivists bring with them unique abilities that can be applied to a disaster situation: a multidisciplinary approach to patient care, management skills, procedural expertise, and flexible attitudes.
7. Intensivists can also provide care outside the domains of the ICU through mobile ICU teams and transport of critically ill patients. Various factors have to be considered in forming such teams and in the safe transport of patients.

Worldwide, there is a need for novel strategies to alleviate the lack of specialized medical care, including critical care medicine. Societal changes in demographics, epidemiology, and culture, as well as significant technological advances, have positioned telemedicine as a useful tool to narrow the gap between available and needed medical care. Thus far, it has been proved to be a disruptive technology, potentially altering traditional paradigms in the critical care environment, particularly in medical education, team organization, medical licensing, quality improvement, disaster response, and research. A recent report estimated that 10% of adult intensive care unit (ICU) beds are covered by some form of telemedicine service.¹ Its relative novelty has resulted in a constant state of flux for available technology, legislation, potential interventions that can be leveraged, and consequently, an ideal model of tele-ICU care. Here we present our perspective for the current state-of-the-art and practical considerations on these matters (Fig. 185-1).

DEFINITION

Telemedicine can be described as the technology-assisted delivery of medical health services from a distance. Potentially related benefits may include improved access and enhanced efficacy, quality, and efficiency in the delivery of healthcare services as well as an equality in distributing scarce resources and the reduction of costs.² Considerable controversy has resulted from the fixation of the health community in the ever-evolving technological aspects of telemedicine, rather than its potential as a tool to leverage otherwise traditional quality improvement interventions.

Although we can track the use of telecommunications with this purpose to the first half of the 20th century in Australia³ and decades later with NASA⁴ and the space race,⁴ it was not until the past 2 decades when critical technological developments allowed for an explosive increase in its use as an alternative for overcrowded traditional models of care.

Traditionally, telemedicine modalities can be classified into store-and-forward, real-time, or remote monitoring. In store-and-forward, medical information is sent electronically to a remote physician for assessment offline, without direct simultaneous interaction between a remote medical team and a telemedicine physician. In the real-time mode, a direct interaction exists between a telemedicine physician (or a physician extender) and a remote patient, physician, or medical team. Finally, remote monitoring implies the monitoring of a patient from a distance using different technologies depending on the physiologic system to be followed.⁵

TELEMEDICINE IN INTENSIVE CARE

The implementation of a new tele-ICU program should focus on each one of the following aspects:

1. Telemedicine-related laws and regulations at state and national levels
2. Technological platform
3. Staffing
4. Model of care

1. Telemedicine-Related Laws and Regulations

There are basic elements that any telemedicine program should consider to comply with national and state laws and technical regulations pertaining to the particularities of the telemedicine interaction (Box 185-1). The American Telemedicine Association has published core guidelines for baseline technical requirements and telemedicine operations, as well as guidelines for tele-ICU operations in particular.⁵ Policies that foster telemedicine use are being promoted in most states (state parity laws) and should be consulted to adjust the tele-ICU program model accordingly, given they will affect reimbursement and credentialing.⁶

In broad terms, signed patient consent must be obtained and patient confidentiality should be preserved at all times regardless of the model of care used in any tele-ICU program. A practitioner licensed in the state where the medical care is being delivered is mandatory during the teleconsultation, and by-proxy credentialing issues should be addressed between connecting hospitals. Moreover, documentation of the telemedicine consult should be in the patient's medical record.

Finally, the unique setting of virtual telepresence results in distinct communication needs that are different from the regular on-site, traditional team interactions, and "telemedicine etiquette" (Box 185-2). They should be kept in mind during telemedicine consultations to be efficient in the art of "the systematic finding and delivery of bad news to the remote team."

2. Technological Platform

A robust information technology department support is needed to ensure seamless communication between the tele-ICU team and remote ICUs.

The cost-efficiency of a tele-ICU technological platform reached a critical point a few years ago, when data transmission migrated from costly dedicated optical cable networks to wireless encrypted communication via Internet.⁷

Depending on the scope of the particular tele-ICU program, minimal hardware could include a simple telemedicine cart on both ends, escalating to fully autonomous robotic telepresence with access to remote electronic medical records (EMRs), medical imaging, and monitoring systems supplemented with automated rapid response algorithms^{8,9} (Fig. 185-2).

3. Staffing

Given the significant disparity between available and needed qualified specialists to meet current safety standards, the Leapfrog group has endorsed telemedicine as an appropriate alternative to reach these goals.¹⁰ It would be wise then to redesign the workflow of the existent and future ICU staffing considering the telemedicine time. In those tele-ICU programs with staff dedicated mainly to telemedicine, a minimum amount of time of direct clinical practice must be ensured to maintain proficiency.

Reimbursement for telemedicine care remains a significant challenge. In a national survey, 55% of respondents reported not billing for

FIGURE 185-1 ■ Telemedicine suite. From left to right panels: Panoramic room cameras, real-time monitoring, real-time connection with telemedicine cart, additional stations for access to remote EMR.

BOX 185-1

Telemedicine-Related Laws and Regulations

National telemedicine laws
State parity laws (U.S.)
Patient confidentiality/consent (Health Insurance Portability and Accountability Act)
By-proxy credentialing

BOX 185-2

Telemedicine Etiquette

- Identify yourself and the remote team
- Ensure patient confidentiality
- Respect the remote team's work
 - Listen to the remote team first
 - Connect in time
 - Keep teleconsultations as brief as possible
- Comply with telemedicine laws and regulations
- Objectively evaluate patient
- Advice based on the best available evidence

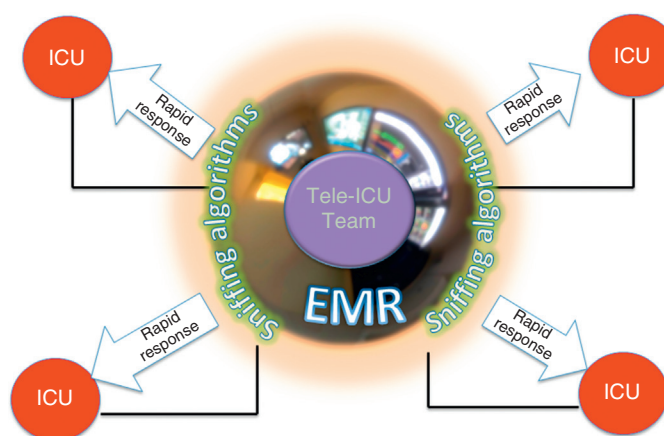

FIGURE 185-2 ■ Diagram of a state-of-the-art tele-ICU. An electronic database with physiologic data and other medical information is updated in real time in the EMR. A tele-ICU team works on surveillance of patient information assisted by remote monitoring, EMR, and sniffer algorithms. Once a dangerous trend is detected, the patient is reviewed with the remote team and a response is elicited.

telemedicine services.¹¹ A number of tele-ICU ventures have jump-started their programs with the assistance of grants. A common arrangement is also a contractual arrangement between connecting hospitals.

4. Model of Care

Tele-ICU in Adult Patients

Different models of care have been adapted for telemedicine in the critical care environment.¹² These models can range from physician-to-physician consultation with limited tele-ICU team involvement to fully autonomous telemedicine team intervention without the need of the presence of a physician in the remote place. Consequently, reports in the intensive care settings have shown conflicting findings related to any effect from a telemedicine system in patient outcomes.¹³

The reason for these discrepancies is not completely understood, and the quality of reported data has been suboptimal. In a systematic literature review and meta-analysis, Young et al. investigated more than 721 critical care and telemedicine articles as well as 2683 critical care or telemedicine abstracts, including 13 studies with more than 41,000 patients in their final analysis. The tele-ICU coverage was associated with a significant reduction in ICU mortality and length of ICU stay but not with in-hospital mortality or length of hospital stay.

There was a significant degree of heterogeneity in the studies included in their analysis and a striking degree of variation in how tele-ICU coverage was defined, the hospitals where it was evaluated, and the impact that tele-ICU coverage had on patient outcomes.¹⁴

Kahn has proposed a conceptual model to describe potential factors influencing the program success (Fig. 185-3). In this model, the effectiveness of a tele-ICU program was influenced by characteristics of both target hospitals and ICUs, as well as the telemedicine unit itself. When optimal, these characteristics may facilitate timely interventions and guideline adherence, leading to improved quality and efficiency of care. When suboptimal, telemedicine fails to change practice patterns and thus fails to improve quality. Identifying optimal characteristics or troublesome ones has proved more elusive.¹⁵

A growing body of evidence has accumulated over the years, suggesting a decrease in mortality and better quality of life associated with implementing tele-ICU programs in the critical care process. Lilly and colleagues, in a multicenter report including 432 patients from 56 different ICUs, observed that those tele-ICU interventions with early intensivists case involvement, adherence to best ICU practices, reduced response times to alarms, as well as encouraged use of performance data were associated with lower mortality and length of stay (Fig. 185-4).^{16,17} Likewise, in a program led by nurses screening best practices in ICU patients, Kahn et al. found improvements in the quality

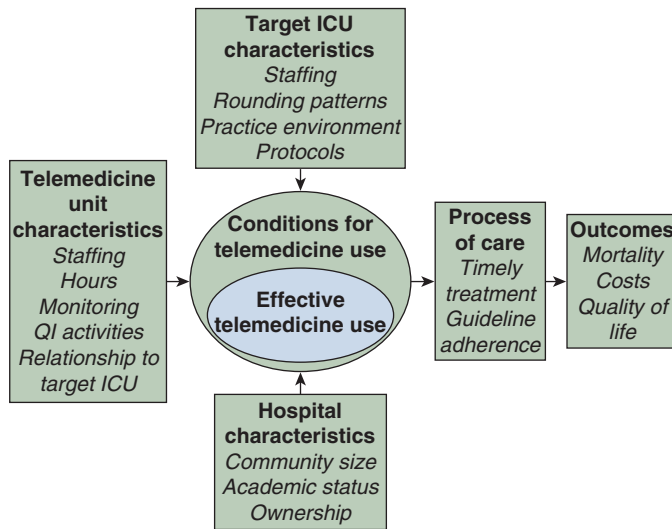

FIGURE 185-3 ■ Conceptual model for ICU telemedicine effectiveness. Under this model, the effectiveness of ICU telemedicine is determined by identifiable characteristics of the target hospital, the target ICU, and the telemedicine unit. QI, quality improvement. (From Kahn JM. ICU telemedicine: from theory to practice. *Crit Care Med* 2015; 42:2457–2458)

of care and a decrease in mechanical ventilation days and length of stay but no impact on mortality.¹⁸

Tele-ICU in Pediatric Patients

The disparity between available and needed expertise in critical care may be even more acute in children. The Institute of Medicine has reported that most children receive emergency care in general hospitals. While children make up for 27% of all emergency department (ED) visits in the United States, only 6% of them are properly equipped for pediatric emergencies. This likely affects the quality of care delivered to children presenting to EDs and, more acutely, in those located in underserved and rural communities.¹⁹

Telemedicine consultation for pediatric critical care shares similarities with the adult setting, as well as differences arising from the unique challenges offered by different and fragmented demographics, a wide range in patient size and physiology, and the coexistence of congenital malformations, among others. Consequently, a verbatim translation of an adult tele-ICU model for these patients may be unworkable, and proper adjustments should be made in maintaining a systematic approach in the teleconsultation format.

Reports related to the use of telemedicine in pediatric ICUs are relatively scarce, with some of them related with critical care consultation to rural and isolated populations. Heath et al. conducted 63 teleconsultations in 10 rural EDs. Most of the communications occurred without significant technical issues, and in 40% of them telemedicine was used to supervise the critical care transport team. A survey reported high satisfaction among consulting and referring physicians, with most of the providers perceiving telemedicine as improving patient care, being superior to telephone conversations, and allowing good provider-to-provider communication.²⁰ Yager et al. reviewed 56 consecutive telemedicine consultations for pediatric patients in the critical care setting. Communications occurred with the pediatric critical care fellow in 100%, nursing staff in 68%, and parents in 66% of their teleconsultations. Patient assessment, communication with multidisciplinary care team, and communication with a patient's family were the outcomes most often cited that would not have been possible via telephone. A change in medical management was noted following 32% of encounters.²¹

The use of an appropriate pediatric tele-ICU can facilitate decision making in remote sites, allowing for a more selective referral of patients to tertiary centers. This is of particular interest in the neonate with cyanosis. In a study from a prospectively collected multicenter database in infants matched for gestational age, weight, and diagnosis, Webb et al. reported that telemedicine shortened the time to diagnosis and significantly decreased the need for transport of infants with mild or no heart disease. They also found that the length of hospitalization and intensive care stay as well as the use of indomethacin and inotropic support were less in telemedicine patients compared with patients in centers without the availability of telemedicine.²²

We have reported our own experience with telemedicine in pediatric cardiac critical care in the international setting, eventually expanding to four hospitals in two Latin American countries. We conducted 1040 teleconsultations for 476 patients, 62% of them being in the most complex surgical patients. There was a difference in overall satisfaction, perception about telemedicine usefulness in education, and impact on medical practice among centers. We concluded that a “one-size-fits-all” approach may not be feasible in most international telemedicine settings, and prospective interventions should consider differences in staff composition, perception of needs, and patient population among centers.²³ In one of the international hospitals participating in our telemedicine program, we conducted a retrospective review of clinical records and a telemedicine database of patients admitted there during the initial 10 months of our program and compared with patients admitted during a preintervention period. We observed a shorter cardiac ICU and length of hospital stay in cardiovascular patients, as well as shorter preoperative and cardiac ICU length of stay in surgical patients.²⁴

Tele-ICU in Disaster Response

Probably one of the most compelling arguments for implementing a tele-ICU program is the continuous training and readiness for disaster response. In such dire situations and despite apparent preparedness, mid-course corrections or the need for improvisation is a common occurrence, including failure in logistics and communications. Although it is true that the very nature of natural or man-made disasters present unique and new challenges in every new presentation, it is also true that many of these problems arise from the fact that, once disaster response plans are made, they often end stored and forgotten, and the teams eventually become untrained. Roberts et al. published their experience with the use of a previously established tele-ICU program for disaster relief during the winter 2009 blizzards in the Baltimore metropolitan area. Given they had been using a telemedicine system for 5 years on a routine basis, they transitioned seamlessly to disaster response mode, conducting daily ICU rounds and coordinated care with the on-site team, assisted by robotic telepresence²⁵ together with remote access to EMR and imaging studies.

TELE-ICU IN THE FUTURE

Tele-ICU is an ever-growing field. The current supply-demand estimates in adult critical care projects a need for tripling the capacity of ICU case days compared with 2006. This is not and will not be sustainable in the foreseeable future.²⁶ Hence, a different paradigm for ICU care needs to be developed. Telemedicine will undoubtedly be an integral part of this new approach, perhaps enabling critical patients to be treated closer to their homes, family, friends, and support network while empowering local teams, providing best-evidence guidelines and quality assurance as well as accelerating the decision-making process to expedite definite treatment or else more compassionate, palliative, or end-of-life care. Integration through a continuum from home and the community to the critical care environment will incorporate early preventive strategies aimed at well-being preservation and risk avoidance, rather than the current reactive approach toward already established critical care disease, connecting presently disjointed practices in ambulatory medicine and critical care.

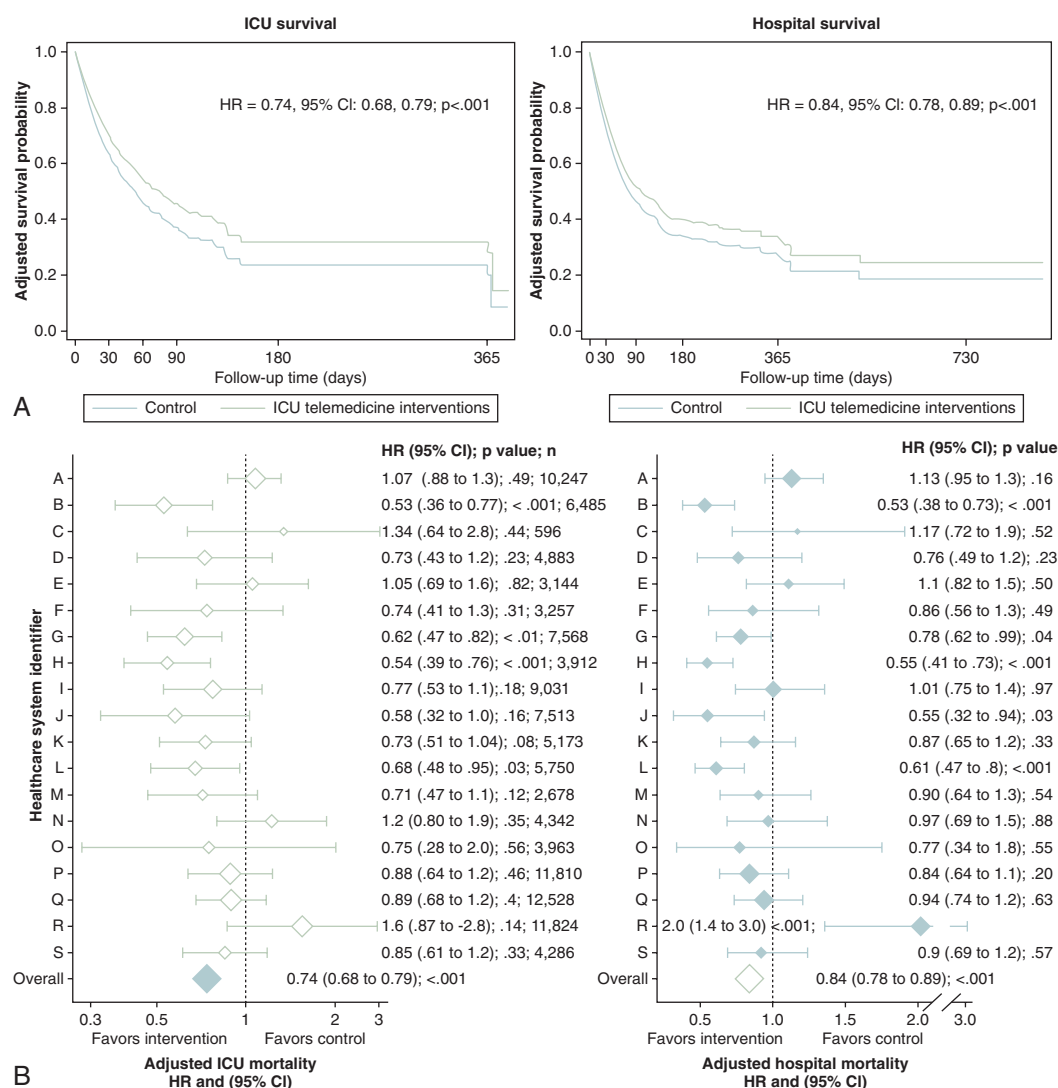

FIGURE 185-4 ■ **A**, Adjusted ICU-specific (*left*) and hospital-specific (*right*) survival estimated by Cox proportional hazards regression. Models adjusted for APACHE IV score, age, hospital, or ICU identifier (as a random effect), admission source, primary admission diagnosis, operative status, time from start of study enrollment, heart rate, admission and highest creatinine values, respiratory rate, admission hematocrit value, blood urea nitrogen, white blood cell count, Glasgow Coma Scale score, prothrombin time, anion gap, urine output (in the first 24 hours), base excess, and total bilirubin and albumin values. **B**, Adjusted ICU-specific (*left*) and hospital-specific (*right*) survival estimated by healthcare system. The center of the diamond represents the effect estimate, the bars represent 95% confidence intervals, the symbol size is proportional to the number of observations for the corresponding healthcare system, and the overall effects are presented as diamonds in the bottom row. HR, hazard ratio. (From Lilly CM, McLaughlin JM, Zhao H, Baker SP, Cody S, Irwin R; UMass Memorial Critical Care Operations Group. A multicenter study of ICU telemedicine reengineering of adult critical care. *Chest* 2014;145:500–507, Fig. 2.)

KEY POINTS

1. Tele-ICU has become a reliable strategy to enhance care in critically ill patients.
2. Fields potentially affected by telemedicine include medical team organization, medical education and licensing, quality improvement, disaster response, and research.
3. Tele-ICU operations should be in compliance with international, national, state, and local laws and regulations.
4. A systematic approach including quality improvement interventions may yield the best results in patient survival and length of stay.
5. Units with low-intensity day staffing may benefit the most from tele-ICU.
6. Pediatric critical patients present unique challenges, but experience is growing rapidly.

Teaching success should be measured in terms of student performance, not the activities of the teacher. Delivering a carefully organized PowerPoint presentation, supervising problem-based workshops, or providing bedside clinical tutorials does not mean one has taught. Unless the learner has acquired new cognitive or psychomotor skills, teaching has not occurred.¹ An effective teacher takes responsibility for ensuring that students learn. If the teacher's perception is that providing a lecture or any instructional methodology fulfills this obligation, then the teacher is serving as "the" educational resource. The focus of this model is on what the teacher did and not on what the learner learned. Said another way, a teacher is someone whose students learn, not one who presents well.

Sritter described a different model, one focused on the student.¹ In this model, the teacher assumes responsibility for the learner's success and creates an environment conducive to learning by managing the educational resources. The teacher as a "manager" creates specific educational objectives, motivates students, utilizes various educational strategies, evaluates learning, and provides effective feedback to ensure the learner achieves all the educational objectives.¹

In the realm of medical education, there have not been significant changes to the principles of effective teaching, teaching theory, or providing feedback. Therefore, many of the topics discussed in this chapter are still relevant, even those described by Bloom, Mager, and many other cited authors with works dating back to the 1960s. What has changed, however, are the learning environments medical trainees face, requirements by medical education governing bodies, and the ways students can learn through advancements in technology. The goal of this chapter is to provide a detailed description of each of these steps, from creating educational objectives to providing feedback, so the teacher can apply the concepts, whether organizing and presenting a 1-hour lecture, a 1-day workshop, a 1-month elective, or a 1-year curriculum.

■ CREATING EDUCATIONAL OBJECTIVES

Educational objectives outline the skills and behaviors the student, resident, or fellow will be able to demonstrate after the teacher has completed a lecture, daily bedside instruction, 1-month elective, or fellowship training. Objectives should be developed for every instructional activity because they are a road map. They guide the teacher in developing an appropriate curriculum, they set unambiguous expectations for the learner, and they serve as a reference for evaluation and feedback.^{2,3}

Developing educational objectives involves three steps.^{2,3} First, using action verbs (e.g., defines, explains, demonstrates, identifies, summarizes, evaluates), the instructor describes a specific behavior the learner must perform to show achievement of the objective. An objective such as "teaches concepts of airway management" is not adequate because it defines what the teacher is doing and does not clearly describe what the learner should be demonstrating. Therefore, it neither serves as a road map for the teacher or the student nor does it identify a clear behavior the teacher can evaluate.

Second, the teacher should describe the conditions under which the behaviors are to occur. For example "given a scenario using human simulation, the student will evaluate the airway and demonstrate effective bag-mask ventilation." Finally, the criteria for acceptable

performance should accompany the objective—that is, "bag-mask ventilation will be followed by successful laryngotracheal intubation within 30 seconds." When written for a lesson plan or formal curriculum, the format of a learning objective should be "who" (learner) will "do what" (knowledge or skill being taught) by "when" (end of lecture, curriculum, or course) as measured by "how" (the method of evaluation).⁴

When teaching students a specific clinical skill—for example, how to manage a patient with hypotension—the teacher must establish that the learner has first mastered the lower cognitive domains, knowledge, and comprehension. This is called *scaffolding* and is based on a classical hierarchy of levels of comprehension described by Bloom.⁵ Learners will not be able to initiate an appropriate treatment for hypotension or evaluate effectiveness of treatment unless they can first list the causes of hypotension and describe the effect of preload on stroke volume. The teacher can ask some simple questions to better understand what level of cognitive domain the student is at, as well as how or why the student is at that point in order to progress to the next level. Using an example from the treatment of heart failure, a teacher could start with a comprehension-level question such as "What is the mechanism of action of furosemide?" This can advance to a higher level, such as analysis, with the instruction "Identify and break down the differences in development, presentation, echocardiography, and treatment for patients with systolic versus diastolic heart failure." At the highest level evaluation, an instruction might then be "Evaluate the evidence to support the role of angiotensin converting enzyme inhibitors in the symptomatology, rates of hospitalization, functional status, and mortality for patients with systolic heart failure."

Educational objectives specifically related to critical care medicine training programs should be developed in accordance with the expectations outlined in the Accreditation Council for Graduate Medical Education (ACGME) program.⁶ In addition to listing the specific cognitive and motor skills that must be taught, the ACGME has developed general core competencies that focus on patient care and not just knowledge acquisition.⁶ The six competencies include medical knowledge, patient care, interpersonal and communication skills, professionalism, practice-based learning, and systems-based practice.⁷ In recent years, the ACGME has evolved from simply assessing trainees subjectively on these competencies, to an evaluation system of milestones with better defined anchors for expected progression based on each clinical specialty.⁷ Examples of educational objectives for each competency and details of each specialty's milestones are available at www.acgme.org.

■ MOTIVATING STUDENTS TO LEARN

The next step in teaching as a manager is to motivate the students to want to learn. To accomplish this they must first value what is being taught. For them to value a specific goal, they need to understand why it is necessary to incorporate the material into their clinical practice.^{8,9} The affective domain addresses educational objectives that relate to valuing and applying the material. For example, the instructor should explain why certain educational goals have been chosen, why they are important, and the consequences of failing to incorporate them. Most important, the teacher needs to be aware of any inadvertent behaviors that may inhibit learning—providing negative feedback in front of

TABLE 186-1 Principles of Adult Learning

Adult learners benefit from:

1. Goal-oriented learning
2. Autonomy and self-directed learning
3. Relevant material to needs
4. Able to practice or trial what is being taught
5. Based on accumulated experiences and knowledge
6. Safe and respectful learning environment

others or demonstrating negative body language, for example. These concepts are consistent with the pillars and principles of adult learning listed in [Table 186-1](#).^{10,11}

The affective domain ties into the student's motivation, with the dichotomy of extrinsic and intrinsic motivators.¹² Extrinsic motivation is when the learner has to be told that an activity needs to occur. In medicine, this can be seen as the difference between studying to pass an examination compared to studying to improve delivery of patient care. Once a learner is able to reach this stage of valuing the learning experience, it not only makes teaching objectives easier for the educator to reach but also sets the stage for life-long learning. This is intrinsic motivation.

A particularly effective tool to get students to both learn and apply their cognitive skills to patient care is to put them in "simulated crisis situations," allowing them to make clinical mistakes and attempt to manage the consequences. Making mistakes in a simulated environment and experiencing the potential complications in real time has proven successful in getting medical trainees to acquire and incorporate cognitive and motor skills into their patient care.

LEARNING EXPERIENCES

There are numerous instructional methodologies a teacher can use to achieve educational objectives. Because adult learners prefer active learning, a curriculum that requires them to process information, participate in problem solving, and defend clinical judgment increases their enthusiasm for learning.⁹

Although frequently used, traditional lectures are not an efficient learning method.¹⁴ There are growing challenges to attending lectures with limited time and competing activities for medical trainees. Moreover, because didactic sessions are not interactive, the teacher does not have an opportunity to assess whether the learner understands the content and its applicability.

Small group sessions that incorporate problem-based learning and interactive workshops are more effective because they engage the students, force them to defend their decisions, and explain how they evaluate outcomes.¹⁴ A more recent development in management of an efficient learning environment is that of the "flipped classroom."^{15,16} A flipped classroom design is one where the students review the core content, such as renal replacement therapy, prior to attending the session and then use the time with the instructor to work through cases or problems and provide direct formative feedback. The growth of recording technology and podcasts provides the opportunity for an instructor to prerecord core content lectures and allow their time in the classroom to be used more efficiently to answer students' questions and work through the material without needing to repeat static elements of the content. Additionally these prerecorded lectures or podcasts can serve as an online reference library for students to return to for review or when they might subsequently encounter a particular topic in clinical practice.¹⁷

However, none of these methods teaches students or residents how to apply these skills to real-life situations. This is of particular importance in the current era where contact hours of exposure to patients are balanced by work hour regulations of medical trainees. Each year 210,000 to 400,000 patients die because of medical errors, an amount increasing from the estimated 98,000 in the landmark study by the Institute of Medicine in 1984.¹⁸ It is possible that giving students an

TABLE 186-2

Learning Objectives for Fourth-Year Critical Care Medicine Course

RESPIRATORY DISTRESS

- Evaluate a simulated patient in respiratory distress (tachypneic and hypoxicemic).
- Initiate appropriate oxygen therapy.
- Evaluate effectiveness of therapeutic intervention.
- Demonstrate effective bag-mask ventilation.
- Insert intravenous catheter for resuscitation.
- Evaluate patient for potentially difficult airway.

CARDIOVASCULAR

- Evaluate a patient with hypotension.
- Initiate therapy for a patient with hypotension (initiate intravenous fluids).
- Order appropriate diagnostic tests for evaluation of a patient with hypotension.
- Evaluate effectiveness of therapeutic intervention.
- Evaluate a patient with sinus tachycardia, develop a differential diagnosis, and order appropriate diagnostic tests.

ARRHYTHMIAS

- Evaluate a patient with sinus tachycardia, develop a differential diagnosis, and order appropriate diagnostic tests.
- Demonstrate defibrillation of ventricular fibrillation and pulseless ventricular tachycardia.
- Demonstrate airway management and cardiovascular resuscitation for simulated patients with ventricular fibrillation, ventricular tachycardia, pulseless electrical activity, and asystole.

opportunity to manage complex problems and anticipate consequences of their interventions in an environment where their mistakes do not result in untoward outcomes, where feedback is immediate, and where students can repeat their performance until they acquire these skills might improve patient safety.

Such instructional opportunities exist and have been available for years in the form of simulation. *Simulation* is defined as any training device that duplicates artificially the conditions that are likely to be encountered in an operation and may include low tech, partial task trainers, simulated patients, computer-based simulation, and whole-body realistic patient simulation. Work in cognitive psychology and education theory suggests that more effective learning occurs when the educational experience provides interactive clues similar to situations in which the learning is applied.¹⁹

What initially began as computerized software with a separate torso apparatus has evolved into complex whole-body computerized manikins. Current models, such as the Laerdal SimMan® 3G simulator provide trainees a high-fidelity manikin that can have spontaneous respirations, palpable pulses, pupils that react to light and can constrict (unequally if desired), sweat, seize, demonstrate cyanosis, and simulate various difficulties for airway management. Moreover, the trainees can practice skills such as bag-valve-mask ventilation, nasal or orotracheal intubations, cricothyroidotomy, chest tube placement, needle decompression, closed chest compressions, cardiac pacing and electrical defibrillation, among other procedures, with real-time feedback provided.²⁰

These computerized human simulators require trainees to integrate cognitive and psychomotor learning, along with multisensory contextual cues to aid in recall and application in clinical settings.^{21,22} Examples of learning objectives for fourth-year medical students and critical care medicine fellows using the simulator are listed in [Tables 186-2](#) and [186-3](#). Note, all objectives are written in terms of behaviors the student must perform, thus giving the teacher clear guidelines for evaluation.

No study has unequivocally demonstrated improvement in actual patient outcomes. Despite not showing these results in published data to present, simulation addresses the fundamentals of adult learning discussed previously. Simulation provides hands-on experiences without any direct risk to patient safety and can simultaneously address

the cognitive, psychomotor, and affective domains of learning that are essential to a successful curriculum. Moreover, organizations such as the Institute of Medicine endorse simulation as a tool to teach novice practitioners problem-solving and crisis management skills.

EVALUATION

Evaluation is an essential component of any education curriculum and should address whether the goals and objectives of the course were met. This refers to evaluating the learners, as well as the educator or curriculum developer. Evaluation tools and standards should be directly derived from the predefined teaching objectives from the curriculum. An educator and his or her curriculum can be deemed

successful if the goals and objectives outlined in the curriculum were completed by the students.²³ Acquisition of knowledge can be evaluated using written examinations. However, they tend to reinforce surface or superficial learning by rewarding students for memorizing facts for recall.

Performance-based examinations can be utilized to assess clinical competency, psychomotor skills, and judgment.²⁴ An example of a performance-based examination is the Objective Structured Clinical Examinations (OSCEs), which were developed by Harden and colleagues in 1975.²⁵ The examinations consist of several "clinical stations," each with its own specific educational objectives. The OSCE requires the learner to recall knowledge, outline a treatment plan, interpret a study such as an electrocardiogram, or perform a specific motor skill. Along these same lines, oral examinations are another example of OSCEs or simulated cases that allow students the chance to defend their decisions or the examiner the opportunity to challenge more advanced decision making from the examinee.^{26,27}

Probably the most common method of assessing clinical competency is to evaluate the learner's performance in real-life clinical situations. Several evaluation tools can be utilized in this environment. Global rating scales are used to evaluate patient care, knowledge application, interpersonal, and communication skills. These evaluations are typically conducted in retrospect and are used to summarize a performance at the end of a clinical rotation. This type of rating has the potential to be highly subjective, and if those performing the evaluation have not been trained, the results may reflect evaluation bias and lose validity.²⁸

Psychomotor skills and procedures are perhaps best evaluated with standardized checklists. Checklists should include the specific behaviors that have to be demonstrated to achieve a satisfactory evaluation.²⁸ Checklists should be developed, and all observers participating in the evaluation should prospectively agree on what constitutes a successful performance (interrater reliability).²⁹ An example of an evaluative checklist for intubation is demonstrated in Table 186-4.

360-degree evaluations and patient surveys are used to obtain feedback on communication, interpersonal skills, and professionalism. However, they are most reliable if there are 20 to 40 patient responses

TABLE 186-3 Learning Objectives for Critical Care Medicine Fellows

1. Assess the patient's airway.
2. Immediately call for help, and follow the difficult airway algorithm if difficulty is anticipated.
3. Have primary and secondary airway strategies available (at least one supraglottic and one subglottic strategy).
4. Demonstrate good head position (sniffing position).
5. Check oxygen source and ensure connection of tubing to oxygen source.
6. Ensure two good peripheral intravenous lines are available and functional.
7. Demonstrate one- and two-person bag-mask ventilation.
8. Use oropharyngeal or nasopharyngeal airway.
9. Establish working suction (check it yourself).
10. Check laryngoscope blades (have size 3 and 4 Mac and Miller blades available).
11. Have at least two sizes of endotracheal tubes available (recommended sizes: 7.0 and 8.0).
12. Check the balloon of the endotracheal tube.
13. Have stylet and CO₂ detector ready.
14. Have medications (etomidate [0.3 mg/kg] and succinylcholine [1 to 1.5 mg/kg] ready in the room).
15. Have two ampules of Neo-Syneprine and 250 mL of D₅W in the room in the event of hypotension.

TABLE 186-4 Respiratory Support

| | YES | NO | N/A | COMMENTS |
|--|-----|----|-----|----------|
| EQUIPMENT PREPARATION | | | | |
| 1. Assembles equipment correctly | | | | |
| 2. Ensures suction is available | | | | |
| DRUGS | | | | |
| 1. Provides adequate/appropriate use of muscle relaxants | | | | |
| 2. Provides adequate/appropriate use of sedative drugs | | | | |
| 3. Provides adequate/appropriate use of topical anesthetics | | | | |
| VENTILATION | | | | |
| 1. Ensures oxygen flow to bag | | | | |
| 2. Preoxygenates patient to 100% | | | | |
| 3. Provides adequate coordination of bag-mask support with spontaneous effort by patient | | | | |
| 4. Provides effective mask seal | | | | |
| 5. Provides effective ventilation by bag-mask | | | | |
| 6. Demonstrates appropriate use of nasopharyngeal or oropharyngeal airway | | | | |
| INTUBATION | | | | |
| 1. Demonstrates appropriate head positioning | | | | |
| 2. Provides cricoid pressure used | | | | |
| 3. Verifies endotracheal tube placement | | | | |
| COMPLICATIONS | | | | |
| 1. Prolonged laryngoscopy complications | | | | |
| 2. Number of intubation attempts _____ | | | | |
| 3. Esophageal intubation (duration in minutes _____) | | | | |
| 4. Bleeding from lip, mouth, nose | | | | |
| 5. Dental injury | | | | |
| 6. Failed intubation | | | | |

per student, which limits the use of this tool.²⁸ In present health care systems, this is a common method for evaluating physicians, such as the Press-Ganey system.³⁰ This could provide trainees early exposure to this form of evaluation, which they will face throughout their future careers.

■ PROVIDING EFFECTIVE FEEDBACK

The final step in being a manager of learning is to effectively utilize feedback to enhance learning. Too often feedback is used to fulfill an administrative function; it is provided as a summative report once the rotation is complete. This is referred to as “evaluative feedback.” Conversely, “formative feedback” is provided in real time with the goal of positively changing a learner’s behavior or skills. Effective feedback enhances affective learning, but when used inappropriately or done poorly, can also inhibit learning.³¹

Students want feedback; they want to know how they are performing and how their performance can be improved. Most students receive inadequate feedback during their training. Explanations for lack of feedback include a teacher’s concerns that the feedback will result in unintended consequences, will damage the student-teacher relationship, or will result in students evaluating the teacher as having performed poorly. None of these consequences will occur if the feedback is delivered correctly. Formative feedback is the only way to ensure the success of students, telling them what they have done well and, if necessary, what they need to do to achieve an educational objective. Without effective formative feedback, the behaviors go uncorrected, and the student develops a system of self-validation: “I did well because no one told me otherwise.”

For feedback to effectively change behavior without causing unintended consequences, several rules should be followed. First, all feedback should be based on how the student performed regarding a specific goal and/or objective of the program.³¹ This is another reason teachers must develop clear educational objectives. They serve not only as the framework for the curriculum but also as a reference for feedback. If feedback is provided in the context of specific performance, there should be no untoward consequence.³¹ For example, if the goal is for the learner to demonstrate effective bag-mask ventilation with appropriate chest excursion and adequate oxygen saturation, then the goal was either achieved or it was not. This is a statement based on an objective and is not a personal affront unless the feedback contains judgmental language. Second, feedback must include a description of how to succeed. In the example presented, if the patient was not effectively ventilated, the teacher should suggest repositioning the head, inserting an oral airway, and performing two-person bag-mask ventilation so there is a better seal with the mask. Third, the specific behavior the learner demonstrated should be addressed and not just interpreted.³¹ If students are late to rounds, do not assume they do not care or are lazy. Stating the expectation that rounds begin at 7 AM and that the expectation is for the trainee to be prepared by then assigns no judgment. Fourth, for feedback to be effective it should be an expected component of the learning tools.³¹ Therefore, the key to providing

TABLE 186-5 Examples of Poor and Better Feedback Comments

| STUDENT'S ACTION | POOR FEEDBACK | BETTER FEEDBACK |
|---------------------------------------|---|---|
| Late for rounds | "When you come late to rounds, you are being lazy." | "Every member of the team is expected to be on time for the start of rounds each morning." |
| Lack of empathy during family meeting | "You were very rude to the patient's wife." | "I noticed that you continued to speak when the patient's wife began to cry. Do you think that would have been a good time to pause and provide empathy through naming her emotions?" |
| Poorly written progress notes | "Your daily progress notes are sloppy and not well written. Do better." | "I noticed in your daily progress notes that you do not describe how or why you chose to treat the patient the way you did, or how he is responding to the therapy. These are some ways to elevate the quality of daily notes. Please try this approach tomorrow and I will follow up with you to see how they improved." |

feedback is for it to be timely and based on an objective behavior, not a subjective trait of the student. Students should be informed during orientation that they will receive daily feedback on their performance of the stated goals and objectives. In summary, feedback should be timely, specific and behavioral-based with suggestions for improvement.³¹ Table 186-5 provides examples of poor and better feedback statements based on these characteristics. Without successfully implementing feedback, the model of teaching described by Irby is incomplete.⁹

■ CONCLUSION

A teacher who begins every educational session with clear objectives, creates an environment where students want to learn, applies different educational strategies, evaluates learning, and provides formative feedback will help his or her students to successfully achieve the educational objectives. These guidelines are applicable for developing a bedside teaching session, a 1-month rotation, or a year-long curriculum for critical care medicine fellows.

■ ACKNOWLEDGMENT

The author would like to thank and acknowledge the contribution of Dr. Paul Rogers for his contributions to the previous edition of this chapter.

KEY POINTS

1. A teacher, serving as a manager, develops educational objectives, motivates students, organizes the curriculum, evaluates performance, and provides feedback.
 2. Educational objectives are an essential component of any instructional activity, setting clear expectations for the learner and serving as a reference for evaluation by the teacher.
 3. Adults prefer active learning; therefore, a curriculum that requires them to analyze, solve, defend, and evaluate increases their
- interest in learning. Medical simulation is an innovative addition to a critical care curriculum.
 4. Developing a valid assessment tool is essential in ensuring that the learner has achieved the educational objectives.
 5. Formative feedback should be provided during instructional activity to ensure the student’s success.

SUPRAGLOTTIC AIRWAY PLACEMENT: BEFORE PROCEDURE

Indications

- Supraglottic airway placement (SGA) use for managing the airway
 - When bag-mask ventilation is ineffective or impossible
 - Noninvasive maneuvers such as nasal and oral airway placement, jaw thrust, chin lift, two- or three-person efforts are ineffective or fail to maintain $\text{SpO}_2 > 90\%$.
 - Decision to utilize a supraglottic airway (e.g., laryngeal mask airway [LMA]) should be made rapidly to avoid desaturation or endangering the patient's safety.
- Primary use when mask ventilation difficulty is anticipated
 - Decision to use an SGA may be based on a known history of difficult mask ventilation. This could be done as a first step in managing the patient. Following preoxygenation with bag-mask assembly, placement of the SGA occurs immediately following pharmacologic induction. Alternatively, topical anesthesia preparation will allow placement of the SGA device; establish effective ventilation, then induce.
 - Suspected difficulty based on Langeron's criteria (two or more factors) + other factors
 - Obesity
 - Edentulous
 - Beard
 - Age >55 years
 - History of snoring, obstructive sleep apnea (OSA)
 - Macroglossia
 - Anatomic alteration of head/neck, dressing, cervical collar
 - Poor positioning
- Secondary use as a rescue airway device when ineffective or impossible mask ventilation exists or following difficult or failed direct or indirect laryngoscopy
 - Following induction of unconsciousness/apnea, bag-mask ventilation not effective
 - Upper airway collapse/obstruction (above supraglottic airway level)
 - Upper airway bleeding (e.g., tongue malignancy), to separate bleeding from lower airway
 - When intubation proves difficult or fails, an SGA can be placed to support oxygenation and then removed for further attempts or used as a conduit for intubation
 - Bridge to support ventilation/oxygenation while other methods are pursued, equipment is gathered, personnel are summoned
 - Ventilation/oxygenation prior to direct laryngoscopy/intubation
 - Fiberoptic bronchoscopy via SGA
 - Retrograde wire intubation: passing wire up through SGA, retrieve wire, remove SGA, advance endotracheal tube (ETT) over wire into trachea
 - Surgical airway (cricothyrotomy, tracheotomy) with SGA in place
- Semiselective use for ventilation/oxygenation support for procedures where bag-mask ventilation known or suspected to be difficult/cumbersome/patient intolerant to procedure without airway

support (e.g., OSA patient for upper endoscopy with moderate sedation)

- Bronchoscopy in patients intolerant to sedation (OSA, obese, debilitated, cardiopulmonary cripple)
- Percutaneous tracheostomy
- Upper endoscopy
- Transesophageal echocardiography (TEE)
- Brief procedure requiring unconsciousness and airway control

Contraindications

- Absolute
 - Airway obstruction (supraglottic and below)
 - Patient unprepared (awake, no topical anesthesia)
 - Elective use with aspiration risk or full stomach
 - Emergency short-term use for rescue of difficult airway is acceptable.
- Relative
 - Anatomic alteration of supraglottic area, glottis, hypopharynx
 - Tumor, abscess, foreign body, swelling
 - Emergency short-term use for airway rescue is acceptable.
 - Pregnancy, obesity, massive/multiple-injured patient
 - Emergency short-term use for airway rescue is acceptable.

Equipment

- Equipment for mask ventilation
- Induction medications, topical anesthesia medications, and equipment for intubation
- Disposable or reusable SGA device
- Lubricating jelly
- Syringe for cuff inflation/deflation
- Tape to secure SGA
- Bite block optional
- SGA includes many available models of the original LMA from LMA North America and the many available other brands with similar offerings.
- Choice of device is often based on cost, comfort with product.
- Evidence-based use exists for some but not all product offerings.
- Sizes range from neonatal to large adult and will vary by manufacturer.
- SGA sizes available should meet needs of patient population in your facility.
- Access to manometer to measure cuff pressure ($<60 \text{ cm H}_2\text{O}$)
- SGA access in facility may be best on code cart, airway cart or bag, rapid-response care cart, resuscitation areas in any and all areas where airway management may take place, either elective, urgent, or emergent.
- In the remote hospital location, SGA devices in a transportable airway bag or tackle box carried by the airway team is an excellent alternative.

ANATOMY

Though there are a variety of SGAs that occupy the periglottic area and surround the glottic opening with a cuff; most models differ very little

except in the manufactured materials, their flexibility or rigidity, ease of use, weight, and effectiveness. Most, but not all (e.g., Igel laryngeal mask) have an inflatable cuff that lies in the hypopharynx and essentially seals the supraglottic region (from the epiglottis down the cricopharyngeal sphincter). A sealed airway allows positive pressure ventilation to be delivered but is limited by the effectiveness of the cuff seal/periglottic mucosal surface interface. Many will allow effective airway pressurization to 10 to 25 cm H₂O pressure before leaking, while other models are specifically designed to allow much higher sealing thresholds (25–35 cm). These latter models are particularly effective in generating ventilatory support for the obese and morbidly obese patient and when confronted by low pulmonary compliance situations (congestive heart failure, acute respiratory distress syndrome, abdominal distention, pregnancy, ascites, and pulmonary fibrosis). Many manufacturers now offer SGA models with a portal that allows passage of a suction catheter or nasogastric tube to assist with evacuation of air or gastric contents from the esophagus and stomach. While handy, access to the aerodigestive tract is not guaranteed nor is the emptying process. Thus, the assumption that these SGA models are acceptable in nonfasting patients or those at risk for aspiration is not supported by published literature. Despite this, any patient who has a failed airway may benefit from SGA placement even if the risk of aspiration is elevated.

In general, placement of the SGA can be performed in the exaggerated “sniff” position to the other extreme, a neutral cervical spine. The SGA generally can be placed effectively when faced with little to no neck flexibility. The SGA is lubricated and then passed toward the roof of the mouth across the hard to soft palate, encouraging smooth advancement along the posterior throat so as to minimize getting hung up on the epiglottis. It typically comes to lie with its distal tip in the cricopharyngeal region. Unfortunately, the cuff end may buckle over on itself, come to lie over the glottic opening, or be displaced in a contorted position that impedes effective ventilation and oxygenation. The SGA may indeed be placed incorrectly but still function in near perfect form with effective ventilation; it is a peculiar airway device. It can be forgiving, yet it still requires skill and finesse to place it properly in most situations. Guidance by a skilled and frequent user is the best method to learn the details of its proper use. Ideally, it lies just over the glottic opening and allows access to the trachea. However, the SGA is frequently malpositioned or the epiglottis is folded over to a lesser or greater degree, partially or completely blocking the pathway to the glottic opening, yet ventilation and oxygenation remain unabated. This may be adequate for airflow to and fro but not for the passage of an ETT into the glottic opening. Hence, most generic SGA models do require fiberoptic-guided placement of an ETT because of the uncertain position of the SGA.

AFTER PROCEDURE

Postprocedure Care

- The SGA used in the semielective, urgent, or emergent setting is often of short duration (2–20 minutes), since the goal is typically to intubate the trachea. Hence the SGA acts as a rescue ventilation device and/or an intubation conduit.

Complications

Complications are not necessarily due to the SGA itself.

- Common
 - Sore throat
 - Complications inversely related to experience skill of operator
- Infrequent
 - Inability to properly insert
 - Inability to ventilate despite proper positioning (laryngospasm, patient biting, kinking of SGA tube), contributing to negative-pressure pulmonary edema
 - Mucosal injury, pressure-induced damage, nerve/vascular injury of airway structures

- Arytenoid dislocation, nerve damage, venous engorgement (all rare)
- Serious, rare complications
 - Obstruction of the glottic opening
 - Regurgitation/aspiration

OUTCOMES AND EVIDENCE

The LMA design offers a relatively short learning curve for the airway novice and affords fewer episodes of desaturation, less difficulty in maintenance of a patent airway, larger tidal volume than mask ventilation, and decreased arm and hand fatigue when compared with a conventional face mask. Its value in the ICU setting for assistance during emergency airway management is undeniable, especially during difficult intubation or when ventilation is not possible with a standard bag-mask assembly. Blind or fiberoptic-assisted tracheal intubation is an extremely attractive asset that the SGA device offers the clinician and provides an entirely novel rescue approach when conventional laryngoscopy and tracheal intubation prove troublesome or impossible. It is also useful in maintaining airway support in the intensive care unit (ICU) setting for patients who require repetitive general anesthetic or heavy sedation-analgesia for brief procedures, fiberoptic bronchoscopy, or diagnostic visualization of the airway. Recent work suggests that the SGA is better tolerated and produces fewer cardiovascular side effects than tracheal intubation. Insertion in the patient with an unstable cervical spine may be far easier than direct laryngoscopy, because its insertion does not absolutely require neck manipulation.

The device may be difficult to place into the hypopharynx in the presence of a small mouth, a large tongue or tonsils, hypertrophied lingual tissue, or a posteriorly displaced pharynx. However, the SGA often proves easier to use than conventional methods of airway control such as direct laryngoscopy. The threat of gastric dilatation and regurgitation/aspiration may lead some to avoid its use in the critically ill, but its excellent track record and very low incidence of regurgitation/aspiration (1/755 emergency insertions, Hartford Hospital, TCM) support its role as a primary airway rescue device when conventional methods fail. The role of the SGA as a rescue device in the elective and emergency setting is unparalleled, but further studies into its use in the emergency setting are needed to solidify its standing as the premier rescue airway device, regardless of which model is used.

BOUGIE-ASSISTED INTUBATION: BEFORE PROCEDURE

Indications

- Exchange of tracheostomy tube
- Exchange of endotracheal tube (ETT) (Warning: most bougie models are approximately 55–65 cm in length and are shorter than the recommended airway exchange catheters. This may present a problem with maintaining control of the bougie during the

exchange, owing to its length [component within the airway and the length outside the mouth available to thread new ETT].)

- Assist with passing ETT into trachea when limited by the “line of sight”
 - Full view of laryngeal inlet (unable to pass ETT because of hang-up on cricoid ring)
 - Full grade I view but a restricted pathway to the glottis—e.g., boggy or edematous tissues, redundant pharyngeal mucosa. Thus, when passing the ETT, the grade I view becomes partially or completely obstructed.
 - Grade II or III view of the larynx with laryngoscopy (conventional)
 - Grade II: posterior third of glottis visible (Lehane-Cormack classification). More detailed classification (Cook-Yentis)
 - Grade III: no cords visible, only epiglottis visible; Cook-Yentis classification
 - Grade IIIa: only epiglottic edge visible
 - Grade IIIb: down-folded or floppy epiglottis is visible
 - Grade IV: no view of any airway structure; bougie use not recommended (Figs. E1-1 through E1-6)
- Combined use with a videolaryngoscope (VAL) to assist with ETT placement
 - Channeled VAL devices (Pentax AWS, AirTraq)
 - Unchanneled VAL devices (GlideScope, McGrath, Storz C-Mac)
 - Very difficult to manipulate the bougie “around the corner” of the models with blades of excessive angulation (GlideScope, McGrath). However, these models promote the likelihood of ETT delivery at an angle such that the tip impinges on the anterior tracheal wall or on the cricoid ring, thus limiting its advancement. Typically,

ETT rotation may allow advancement, but bougie placement via the ETT may allow the bougie tip to slip off the impingement and allow ETT passage.

- Excellent adjunct with conventionally shaped “Video C-Mac”
- Useful if ETT is located just proximal to glottic opening and the bougie is passed through the existing ETT and then manipulated into the trachea
- Use of the bougie to determine the location of the ETT (esophagus vs. trachea)
 - Hang-up test (Cheney’s sign)
 - Bougie tip will hang up on carina or main stem bronchus, compared to simply passing unimpeded into the esophagus.
- Useful in cardiac arrest or clinical situation in which it is difficult to discern proper ETT placement—i.e., cardiac arrest with no detectable EtCO₂ or access to such devices.

Contraindications

- Unfamiliar with its use
- Recent tracheobronchial reconstruction

Equipment

- A tracheal tube introducer “bougie” is an inexpensive, disposable, easily transportable airway device that requires minimal setup time, no battery or electrical power, and is noted on all the major airway-management algorithm lists of desired airway devices that should be immediately available.
- A variety of manufacturers offer bougie models in 55- to 65-cm length.
- Solid and hollow bougie models are offered by some manufacturers.
- Distinct black markings along the length of the bougie assist the clinician with the depth of insertion.

FIGURE E1-1 ■ Line of sight with direct laryngoscopy.

FIGURE E1-3 ■ Cook-Yentis grade IIb laryngeal view with direct laryngoscopy achieves a very high success rate with bougie-assisted intubation.

FIGURE E1-2 ■ Lehane-Cormack laryngeal view grading system with the Cook-Yentis modifications, grades I→IV.

FIGURE E1-4 ■ Cook-Yentis grade IIIa view with direct laryngoscopy achieves a respectable success rate with bougie-assisted intubation, especially when compared to blind passing of the endotracheal tube “around the corner.”

FIGURE E1-5 ■ A grade IV view, essentially no view at all of the laryngeal structures. The bougie is not indicated for a grade IV view though in experts’ hands and following failure of other techniques, careful blind passage combined with detection of tip hang-up (carina, main stem bronchus) may allow blinded intubation. This is a last ditch effort maneuver and is not recommended as a routine approach. It is best handled with an SGA, flexible fiberoptic bronchoscopy (FFB), or video-assisted laryngoscopy (VAL).

FIGURE E1-6 ■ Two bougie models are shown (tracheal tube introducer). Note the characteristic 30-degree angle. The Coude tip allows manipulation of the bougie underneath the epiglottis to increase its rate of passage through the laryngeal opening.

FIGURE E1-7 ■ A grade IIIb view; floppy or overhanging epiglottis may be difficult to navigate around with a variety of airway adjuncts. The bougie may be used to elevate the epiglottis and navigate into the trachea, but the success rate is substantially lower in the grade IIIb setting (30%-50%) compared to a grade IIIa (only leading edge of epiglottis visible, 80%-90%).

ANATOMY

Though the bougie is capable of assisting intubation in nearly all airway situations except when “no view” is possible, it is most commonly used as an adjunct with grade IIb, IIIa, and IIIb laryngeal views. Even when the laryngoscopy reveals a full view (grade I), the bougie may be useful when the hypopharyngeal opening is narrow (OSA, obesity, swelling) and passing the ETT may actually obstruct the view of the glottic opening. In this case, the narrower, more colorful tracheal tube introducer can be passed into the trachea with little visual obstruction taking place. Conversely, the floppy epiglottis is a challenge that may be technically difficult with many different airway adjuncts. The bougie may either be used to elevate the floppy epiglottis or be maneuvered around by virtue of the Coude tip. Though useful, the success rate is often less than 50%, and other airway device alternatives may be needed (intubating laryngeal mask airway [ILMA], VAL, flexible fiberoptic bronchoscope [FFB] (Fig. E1-7).

PROCEDURE

- The bougie is grasped in the intubator’s right hand at the 20- to 25-cm mark.
- It is passed alongside the laryngoscope with the 30-degree angled tip (coude) anteriorly.
- The tip is advanced anterior to the arytenoids and into the larynx (grade IIa, IIb).
- The tip is then advanced underneath the epiglottis and past the vocal cords blindly (grade IIIa).
- The tip lifts the floppy epiglottis and is then advanced blindly past the vocal cords (grade IIIb).
- Following advancement into the trachea to a depth of 22 to 26 cm in an average adult
 - Tip may “bounce” or “click” past the tracheal rings, suggesting tracheal placement.
 - This is a helpful sign but does not guarantee intratracheal placement.
 - Conversely, the lack of “clicks” does not guarantee the position of the bougie, nor does it rule out location within the trachea.
- 10%-50% of bougies passed into a grade III airway may enter the esophagus
 - Grade IIIa: 5%-12% may enter the esophagus
 - Grade IIIb: 30%-50% may enter the esophagus
 - Quickly deploy backup strategy (SGA, FFB, VAL)
 - Some may consider bougie a poor choice in grade IIIb view.
- Tip may be gently advanced farther (28-36 cm) to contact carina/main stem bronchus
 - Tip hang-up provides tactile feedback during blind passage.
 - Detection of carina/bronchus is reassuring to operator.
 - Advancement past 35-40 cm without hang-up strongly suggests the bougie is in the esophagus.

FIGURE E1-8 ■ Endotracheal tube (ETT) being passed over tracheal tube introducer (TTI, bougie) and getting hung up on the epiglottis and arytenoid. Continued advancement should be discouraged. Simply withdraw 1 to 2 cm, rotate ETT counterclockwise about 90 degrees, and re-advance. VC, vocal cord.

- Using hang-up or Cheney's sign lowers the incidence and dangers of passing the ETT into the esophagus.
- Eliminates the delay of verifying the ETT location by insufflation, capnography, auscultation
- Decision time: passing the ETT
 - If time permits, generously lubricate the ETT.
 - Smaller sized ETTs pass over the bougie more easily than larger ones.
 - Maintain tongue displacement with laryngoscopy/hand grasp.
 - Pass the ETT, but do not force the advancement (an assistant should grasp the proximal end of the bougie to stabilize it).
 - Anticipate resistance at 16- to 17-cm depth due to impingement on arytenoid/vocal cord (2 methods to remedy this) (Fig. E1-8).
 - Preemptively advance ETT while rotating in the counterclockwise (CCW) direction to allow ETT to avoid impingement on the glottis.
 - If resistance is encountered, stop and withdraw ETT 2 cm and then rotate CCW and advance the ETT into the airway.
 - If ETT fails to pass, the patient may be ventilated and oxygenated with bag-mask ventilation (move the bougie to the corner of the mouth).
 - Change to a smaller diameter ETT (to ease advancement over the bougie), and assume the glottic opening may be swollen, impeding entry.

AFTER PROCEDURE

Postprocedure Care

- Following advancement of ETT into the trachea, stabilize the ETT in position, and remove the bougie.
- Standard methods of determining the ETT position are required.

Complications

- Inability to pass the bougie underneath the epiglottic edge (grade IIIa) or inability to lift the down-folded or floppy epiglottis (grade IIIb)
 - Depending on the skill and experience of the operator and the condition of the patient, time spent advancing the bougie should be limited so as not to endanger the patient's condition (SpO₂).
 - If unsuccessful, quickly move to another accessory device to secure the airway.

- Infrequent
 - Minor tissue injury, airway trauma
 - Esophageal placement of bougie
 - Esophageal intubation (the hang-up test should eliminate this hazard)
- Serious, rare complications
 - Mucosal laceration, bronchial/carina perforation if extreme force is applied to bougie advancement or the patient's underlying airway anatomy is compromised/diseased

OUTCOMES AND EVIDENCE

The simplicity of the trachea tube introducer makes it an attractive option for assisting with trachea intubation in the situation when a restricted laryngeal view is available with laryngoscopy. A variety of uses for the bougie make it a desirable addition to the difficult airway cart or bag, made accessible at the bedside in the ICU and other remote locations in the hospital. The bougie is a suggested option in the management algorithms offered by anesthesiology societies in the United States, Canada, the United Kingdom, Germany, and many other countries.

INTUBATING MODEL OF THE SGA FOR EMERGENCY AIRWAY RESCUE (LMA MODEL [FASTRACH] INTUBATING LMA [ILMA] WILL SERVE AS AN EXAMPLE BUT OTHER BRANDS ARE AVAILABLE): BEFORE PROCEDURE

Indications

- Emergency rescue of the airway when tracheal intubation is the goal
 - Failed conventional intubation attempts
 - Failed bougie-assisted intubation
 - Failed VAL intubation
 - May be a substitute for conventional SGA device following its failure to secure successful ventilation/oxygenation

Contraindications

- Inexperienced operator/airway team
- Major risk for regurgitation/aspiration (relative; loss or lack of airway is worse)
- Oral cavity inaccessible/trismus
- Similar to other SGA devices

Equipment

- Equipment for mask ventilation
- Induction medications, topical anesthesia medications, and equipment for intubation

- Disposable or reusable models of the ILMA, ETT, and stabilizing rod
- Lubricating jelly
- Syringe for cuff inflation/deflation
- Tape to secure SGA
- Bite block not needed
- Manometer to measure cuff pressure (<60 cm H₂O)

ANATOMY

The ILMA is similar to other SGA devices that occupy the periglottic area and surround the glottic opening with a cuff. Passing the ILMA into the oral cavity is easier than the comparative standard LMA, since it is designed with an intrinsic curve easing passage into the hypopharynx. The inflatable cuff lies in the hypopharynx and essentially seals the supraglottic region [from the epiglottis down to the cricopharyngeal (upper) sphincter]. The rigid construction of the ILMA is limited by its diameter, so adequate mouth opening is a prerequisite. The sealed ILMA allows positive-pressure ventilation to be delivered. Occasionally, the ILMA will afford effective ventilation if the standard LMA model fails, and vice versa (as could other brands).

In general, placement of the ILMA can be performed in the exaggerated “sniff” position or the other extreme, a neutral cervical spine. In the presence of cervical spine immobility, it is best to maintain stabilization yet remove the front collar to improve oral access. Following cuff deflation, the ILMA is lubricated and then passed along the roof of the mouth across the hard to soft palate, encouraging smooth advancement along the posterior throat so as to minimize getting hung up on the epiglottis or causing its down-folding. The distal tip of the ILMA typically comes to lie in the cricopharyngeal region. Unfortunately, the cuff end may buckle over on itself, come to lie over the glottic opening, or be displaced in a contorted position that impedes effective ventilation and oxygenation (Figs. E1-9 through E1-16).

PROCEDURE

- The ILMA is placed into the airway in a similar fashion as other LMA products. However, the shortened length of the ILMA model and its handle may be simpler to place than the standard LMA model. Placement is augmented by passing it along the hard to soft palate posteriorly into the hypopharynx, posterior to the epiglottis. It too comes to lie with its tip atop the cricopharyngeal area posterior to the arytenoids/glottis. The tip may fold over or under and impede air exchange or be sensed by an incomplete cuff seal (leak). This can be remedied by performing the “in-and-out” or “up-and-

down” maneuver (simply moving the ILMA slightly inward and outward to free up the distal tip). Cuff inflation is followed by positive pressure oxygen delivery. Successful placement allows chest rise, ETCO₂ detection, with no audible air leak to approximately 15 to 25 cm H₂O pressure applied to the ILMA. Always confirm ventilation prior to attempting ETT advancement via the ILMA.

- Two maneuvers are handy to improve success in ILMA placement and intubation.
 - Following ILMA placement, Chandy maneuver #1 involves using the ILMA handle to optimize the positioning of the ILMA within the airway, with the goal of maximizing tidal volume, ETCO₂, and the feel of “bagging.” The ILMA is held in this position in preparation for passing a lubricated ETT. The included LMA brand wire-reinforced ETT is an excellent ETT for passing, but it is suboptimal for long-term use in the ICU airway (if

FIGURE E1-10 ■ Swing the mask into place in a circular movement, maintaining contact against the palate and posterior wall of the pharynx. Do not use the handle as a lever.

FIGURE E1-11 ■ Inflate the mask, without holding the tube or handle, with approximately 10 to 20 mL of airway to seal the airway. Apply a manual bag or anesthesia circuit and verify ventilation. If no ventilation (leak or resistance), assume misplacement of ILMA or down-folding of the epiglottis. Manipulate the ILMA in an up-and-down or in-and-out maneuver to optimize position. Recheck ventilation, and adjust location of the ILMA to optimize ventilation. Do not attempt passing the endotracheal tube until effective ventilation is ensured.

FIGURE E1-9 ■ Deflate the cuff, and lubricate with a water-soluble lubricant on the posterior surface. The lubricated intubating laryngeal mask airway is passed over the hard to soft palate along the posterior pharyngeal wall to the point where gentle resistance is felt.

FIGURE E1-12 ■ Hold the ILMA handle while gently inserting the lubricated endotracheal tube (ETT) into the airway shaft. The provided ILMA-ETT is best suited for this, though a well-lubricated standard ETT may be used with fiberoptic guidance or may be used (with proper training and experience) blindly by inserting it “backward,” meaning the concave curve of the ETT faces the nose as it is advanced into the ILMA shaft.

FIGURE E1-14 ■ Remove the ETT connector, and place the provided stabilizing rod onto the end of the ETT. Then ease the ILMA over the existing ETT and rod by gently swinging the handle caudally (keeping the ETT stable in position) until the ETT can be grasped at the level of the incisors.

FIGURE E1-13 ■ Advance the ETT, inflate the cuff, and confirm intubation. If unable to pass, ensure adequate lubrication. If resistance is felt, the ILMA may be malpositioned or may have entrapped the epiglottis and thus block ETT advancement. Try the in-and-out maneuver to reposition the ILMA and free up the epiglottis if applicable.

FIGURE E1-15 ■ Remove the stabilizing rod, and gently unthread the inflation line and pilot balloon of the ETT. Replace the ETT connector, and confirm ventilation and position per standard intubation procedures. If the ILMA has been used on a very challenging airway or the patient is unstable, delay removal of the ILMA from the existing ETT until stabilization takes place. Extubation of the airway is possible, so this maneuver should only be performed by those skilled in its execution.

duration of intubation is >24-48 hours, one should consider changing the ETT over an airway exchange catheter to the standard ICU ETT model).

- Once effective ventilation/oxygenation is established, passing an ETT may be the next objective. With the ILMA in the best ventilating position (Chandy #1), Chandy maneuver #2 involves using the ILMA handle to slightly elevate or “lift” the ILMA (handle toward forehead, ILMA distal tip anteriorly) to improve the success rate of passing the ETT into the trachea, based on the ILMA portal being tilted toward the glottic opening and away from the esophagus. This lift increases seal pressure and improves the alignment of the ILMA to the glottic opening and corrects any flexion the mask has undergone following its placement. Malposition or flexion of the mask while in the ventilating position may alter the pathway of the ETT as it exits the ILMA. Generous lubrication of the ETT to ease passage through the ILMA lumen is absolutely essential. Intubation of the trachea

may be performed blindly or with fiberoptic assistance. The skill to successfully intubate the trachea is attained by practice coupled with instruction by an experienced individual. Practicing the technique before an emergency situation arises is in the best interest of patient care.

- Troubleshooting in the event of failure to intubate (typically caused by a down-folded epiglottis, ETT impaction on the periglottic tissues, too large or too small ILMA, or patient is resisting intubation because of inadequate sedation/analgesia/muscle relaxation/anesthesia)
- If resistance is felt approximately 2 cm beyond the black transverse line marked on the ILMA ETT (or 15-16 cm marking on

FIGURE E1-16 ■ Cook Critical Care prepackaged retrograde wire intubation kit. Use of the ILMA should be learned prior to its deployment in an emergency airway crisis. Training on a mannequin or humans under elective conditions by a skilled practitioner is best.

a standard ETT), the down-folded epiglottis may be blocking ETT advancement, as may the vestibular wall. Rotation of the ETT may allow passage if impeded by the vestibular wall. A down-folded epiglottis may need to be addressed by performing the “up-and-down” maneuver. This is a partial withdrawal of the inflated ILMA to a maximum of 6 cm, followed by reinsertion. This often frees the epiglottis from its down-folded position. Otherwise, FFB assistance is needed, or a different size ILMA may be tried.

- If the ETT meets immediate resistance at 15 to 16 cm (black mark) or at 4- to 5-cm depth past the black mark, then the ILMA is too large, and downsizing may help.
- If resistance is encountered at 3 cm past the black mark, the ILMA may be too small. If an alternative-size ILMA is not available, external manipulation of the larynx either downward or caudally may assist with passing the ETT. Likewise, ETT rotation may be helpful.
- The ILMA has an “epiglottis elevator bar” to assist in lifting the epiglottis up to afford improved ETT passage into the laryngeal inlet. When using bronchoscopic-guided ETT advancement, using the ETT tip to elevate the bar is best since the bronchoscope typically is not rigid enough to do so by itself.
- Another miscellaneous yet quite important clinical situation that may prohibit intubation is excessive periglottic/glottic edema when viewing with the FFB. Massive airway edema may preclude advancement of the FFB-ETT owing to the inability to clearly identify the glottic opening; caution must be exercised to not advance the FFB tip into unrecognizable tissue planes. Excessive force on the FFB or ETT may lead to tissue injury and thus threaten the current airway patency by inducing further bleeding, edema, or swelling. Attaching a bronchoscopic swivel adapter to the ILMA itself or via the ETT may allow active application of positive pressure to the airway and promote lateralization of the edematous glottic tissues. This is analogous to the use of continuous positive airway pressure (CPAP) in OSA patients. The bronchoscopic adapter is too narrow to allow an ETT to pass through it. To remedy this, an Aintree catheter (bougie-type catheter with a lumen that allows a proper sized FFB to be placed within the catheter) is sized to fit through the adapter and its diaphragm. The Aintree-FFB assembly may be passed through the bronchoscopic adapter, down the ILMA, and used to visualize the glottic opening. Once advanced into the trachea, the Aintree remains within the trachea as the FFB is withdrawn. The ILMA is then removed over the Aintree, and the ETT is advanced over the Aintree catheter in similar fashion to a bougie, tube exchanger, or FFB.

AFTER PROCEDURE

Postprocedure Care

- Following “blind” intubation of the trachea, standard methods to confirm ETT position are pursued (chest auscultation, EtCO₂ detection, ETT misting, chest rise, etc.).
- Following fiberoptic-assisted intubation, the same clinical confirmation of ETT position should be pursued, even though visualization of the ETT within the trachea with FFB is considered failsafe. The caveat here is that FFB confirmation, though failsafe under ideal conditions, may be limited by secretions, edema, soilage, operator inexperience, faulty battery power, and other limitations seen in the ICU airway.
- With the ETT-ILMA assembly in place, the ILMA has to be carefully removed from the patient while leaving the ETT within the trachea. Accidental tracheal extubation during ILMA removal could be disastrous.
- Step-by-step removal of the ILMA is outlined later.
- If one is unfamiliar with ILMA removal, a more experienced team should be summoned to assist with this task. Conversely, if the patient’s clinical condition needs to be stabilized prior to its removal, at a minimum, the air should be removed from the ILMA cuff (leaving the ETT cuff inflated) to reduce the pressure effect on the pharyngeal mucosa.

Complications

- Common
 - As outlined under SGA
 - Inability to establish ventilation/oxygenation
 - Inability to intubate the trachea
 - Esophageal intubation
 - Obstructed advancement of the ETT through the ILMA
- Infrequent
 - Dental damage, mucosal injury
- Serious, rare complications
 - Regurgitation/aspiration (very rare)

OUTCOMES AND EVIDENCE

- The use of the ILMA has revolutionized airway management, especially in the emergency setting. It is an accepted component in the American Society of Anesthesiologists (ASA) airway management algorithm, as well as all other algorithms offered by medical societies throughout the world. The presence of VAL has potentially altered the ILMA’s role as a logical and rational first step toward airway rescue when conventional methods fail or are inappropriate. However, the clinician must be familiar with this device and have it readily available as a backup for VAL difficulties or failures.
- In the elective setting, the ILMA has an excellent track record for a high level of successful ventilation coupled with blind and FFB-assisted intubation. Its successful deployment in the acute care setting in the ICU, the emergency department, or other remote locations outside of the operating room has been well received, though the success rate for both ventilation and intubation is tempered to a more realistic success rate of nearly 8 to 9 out of 10 patient encounters (Hartford Hospital database, TCM). Thus, a backup plan must be in place to deal with ILMA failure and establish effective ventilation/oxygenation and ultimately tracheal intubation, either blindly or with FFB assistance.

RETROGRADE WIRE INTUBATION: BEFORE PROCEDURE

Indications

- Secure the airway in the elective setting with the patient awake, with adequate local anesthesia topicalization or nerve blocks
 - Trismus, severe temporomandibular joint (TMJ) disease, limited cervical range of motion
 - Known difficult mask ventilation, intubation
- Secure the airway emergently in the setting that mask ventilation/oxygenation is effective
 - Retrograde wire-guided intubation, in the best situation, may require 2 to 5 minutes to complete; hence one must be able to maintain successful ventilation/oxygenation.
- Considered an effective airway rescue in the nonemergent pathway on the ASA difficult airway algorithm (*cannot* intubate, *can* ventilate) when oral or nasal intubation is impossible or failed for a variety of conditions
 - Any reason the patient is a “difficult airway”
 - Massive oral, nasal, or pharyngeal hemorrhage (must be able to locate wire)
 - Trismus (must open at least one fingerbreadth)
 - TMJ abnormalities limiting mouth opening (must open at least one fingerbreadth)
 - Structural deformities of oropharynx, congenital or acquired
 - Mass (cancer, tumor, polyp, or other if not directly in line of wire advancement)
 - Traumatic injuries making oral/nasal tracheal intubation difficult or impossible
 - Maxillofacial injuries
 - Cervical spine instability
- Secure the airway electively when difficult airway factors are known or suspected to exist and intubation by other means may be difficult or impossible.

Contraindications

- Absolute contraindications
 - Transection of trachea with retraction of distal end into the mediastinum

- Fracture or other significant injury of the larynx or cricoid cartilage
- Infection, cancer, mass at site of wire insertion (cricothyroid membrane) or in pathway of wire advancement
- Unfamiliarity with the procedure
- Relative contraindications*
 - Infants and toddlers (<3 years)
 - Bleeding diathesis
 - Patients with massive neck edema, lack of landmarks

Equipment

- Guide wire (suggested >60 cm) matched to appropriate needle size allowing advancement
- 20-, 18-, 16-, or 14-gauge cutting needle on a syringe
- Cuffed 6.0 endotracheal tube
- Hemostat or Kelly clamp
- Alternative: manufactured retrograde wire intubation kit (Cook Critical Care) (see [Fig. E1-16](#))
- Optional: FFB

ANATOMY

The cricothyroid membrane is located between the superior thyroid cartilage and the inferior cricoid ring. The cricothyroid membrane is located just 1.5 to 2 cm below the vocal cords, so care must be practiced when advancing a needle caudad, as the underside of the vocal cords could be impaled. Passing the ETT over the wire or obturator/wire may be met with resistance at the 16- to 17-cm depth, as the ETT tip may impinge on the vocal cords or arytenoids. This is the inherent danger of passing the ETT blindly over the wire or obturator/wire assembly. The location of the distal tip (having met resistance) may or may not be at the position below the vocal cords. This is the challenge of the retrograde wire method; knowing the location of the ETT tip is unknown when the decision is made to remove the wire. If the ETT tip is erroneously positioned above the glottis, then the access to the airway is denied with wire removal; hence, the advantage of using the FFB as an intubation guide ([Fig. E1-17](#)).

FIGURE E1-17 ■ Anatomic landmarks for access to the cricothyroid membrane.

*Relative contraindications may be overlooked in the emergency situation.

PROCEDURE

- Retrograde tracheal intubation
 - Needle insertion directed cephalad; operator should approach with dominant hand more caudad (e.g., right-handed operator on right side of patient)
 - Puncture cricothyroid membrane with needle directed cephalad (Fig. E1-18). Aspirate air with syringe to locate air column (1-2 mL of saline in syringe; allow bubbles to percolate to verify the air column).
 - Pass the guide wire through needle aimed superiorly so that distal end of wire may be retrieved from mouth (or if desired, nose) of patient. Withdraw needle off wire
 - Pull majority of wire out of the mouth (or naris)
 - Secure distal end of wire by clamping hemostat at level of the cricothyroid membrane (Figs. E1-19 and E1-20).
 - Three choices to pass ETT down the wire into the airway (nasal or oral): (1) wire assisted, (2) wire with obturator to reinforce wire, (3) flexible bronchoscope (loaded with ETT) passed over wire into airway
 - Wire assisted
 - Load lubricated ETT over oral (or nasal) end of wire, passing wire into tube through Murphy's eye.
 - Pull wire relatively taut and straight.
 - Advance ETT over wire into trachea to cricoid area and then, gradually relaxing cricothyroid end of wire, advance ETT to appropriate intratracheal location.
 - Release cricothyroid end of wire, and withdraw wire out of ETT.
 - Confirm ETT position (auscultation/capnography).
 - Wire with obturator to reinforce wire (Fig. E1-21)
 - Pass obturator over wire into airway until resistance is felt.
 - See manufacturer's instructions for Cook retrograde intubation kit.
 - Load lubricated ETT over oral (or nasal) end of wire/obturator.
 - Advance ETT into trachea to cricoid area.
 - Remove wire from cricothyroid membrane end, and then advance obturator distally into trachea.
 - Advance ETT to appropriate intratracheal location.
 - Confirm ETT position (auscultation/capnography).
 - FFB (loaded with smaller sized ETT [6-7 mm]) (Fig. E1-22)
 - Advance wire through the suction portal of the FFB.
 - Grasp wire end from top of FFB.
 - Advance FFB down wire, observing the airway structures as you advance (Fig. E1-23).

FIGURE E1-18 ■ Puncture of cricothyroid membrane, with air aspiration reflected in bubbling in saline-filled syringe.

FIGURE E1-20 ■ Advancing the wire from the neck to the oral cavity.

FIGURE E1-19 ■ Locating and retrieving the retrograde wire within the oral cavity.

FIGURE E1-21 ■ Passing the Cook obturator over the retrograde wire to reinforce the wire to allow ease of passing the ETT into the airway.

FIGURE E1-22 ■ A better choice than the obturator is the FFB passed over the wire via the suction port of the fiberoptic bronchoscope.

FIGURE E1-23 ■ Retrograde wire seen emerging from glottis.

- Advancing the FFB to distal end of wire will occlude view and appear “pink” (backside of cricothyroid membrane). Correct position may be verified by darkening the room to transilluminate the cricothyroid membrane puncture site (Fig. E1-24).
- Once the FFB is below the vocal cords, the cricothyroid end of wire may be released as fiberscope is advanced to carina and wire and then pulled out of fiberscope.
- Or the wire may be pulled out inferiorly through cricothyroid puncture and fiberscope and advanced into the trachea.
- Advance the FFB tip into distal trachea, and advance ETT into position and confirm.

■ AFTER PROCEDURE

Postprocedure Care

- Following advancement of ETT into the trachea, stabilize the ETT in position.
- Standard methods of determining the ETT position are required.

FIGURE E1-24 ■ Flexible fiberoptic bronchoscope (FFB) passed over retrograde wire, with tip of FFB at wire insertion site at the cricothyroid membrane, with transillumination of light from the FFB.

Complications

- Inability to locate wire in oral cavity/nose
 - Use light (e.g., laryngoscope) to assist locating wire
 - Pick up wire with hemostat
- Infrequent
 - Tissue injury when picking up wire with hemostat
 - Hematoma from injury to the cricothyroid artery
 - Subcutaneous emphysema
 - Infection at site of insertion (rare)
 - False tract from passing wire
- Serious rare complications
 - Possible airway obstruction, loss of airway, laryngospasm

■ OUTCOMES AND EVIDENCE

Retrograde intubation, once a prominent adjunct prior to today's many varied airway devices, retains an important position in managing the difficult airway, but it has been relegated to a much less prominent role. It is important for clinicians to maintain the ability, knowledge, and equipment to perform this specialized method of securing the airway. Even in the best of clinical situations and manned by an experienced team, this method remains a relatively time-consuming technique that limits it to the nonemergency pathway, where ventilation/oxygenation is possible with either bag-mask ventilation or SGA or the patient is awake breathing spontaneously.

NEEDLE CRICOTHYROTOMY WITH TRANSTRACHEAL JET VENTILATION: BEFORE PROCEDURE

Indications

(Similar to cricothyrotomy)

- Impossible or failed oral or nasal endotracheal intubation owing to any of the following
 - Difficult or impossible intubation (CVCI: cannot ventilate, cannot intubate)
 - Massive oral, nasal, or pharyngeal hemorrhage
 - Massive regurgitation or emesis
 - Masseter spasm, clenched teeth, TMJ limitations
 - Structural deformities of oropharynx, congenital or acquired
 - Stenosis/narrowing of upper airway
 - Mass (cancer, tumor, polyp, or other) with partial obstruction
- Airway obstruction (partial but not complete) above cricothyroid membrane
 - Nontraumatic versus traumatic
 - Oropharyngeal edema
 - Mass (cancer, tumor, polyp, or other) (Fig. E1-25)
 - Traumatic
 - Foreign body obstruction
 - Stenosis
- Traumatic injuries making oral or nasal endotracheal intubation difficult or potentially hazardous
 - Maxillofacial injuries
 - Cervical spine instability

FIGURE E1-25 ■ Classic example of when not to incorporate transtracheal jet ventilation (TTJV). This intratracheal tumor mass occludes more than 85% of the tracheal lumen. Providing high-pressure TTJV supports oxygen transfer into the pulmonary tree, but overpressurization of the thorax will likely occur, because egress of the transmitted pressure may be blocked by the mass and its potential ball-valve effect. Likewise, a glottic or subglottic mass (above the site of needle insertion) may equally disallow egress or relief of the pressure buildup with high-pressure TTJV, thus leading to barotrauma.

Contraindications

- Absolute contraindications
 - Endotracheal intubation can be accomplished easily and quickly, and no contraindications to endotracheal intubation are present.
 - Transection of trachea with retraction of distal end into the mediastinum
 - Fracture or other significant injury of the larynx or cricoid cartilage
 - Lack of egress of pressurized airflow (exhalation, must insure good air in, bad air out) resulting in inability to relieve pressured insufflation from trachea
- Relative contraindications*
 - Infants and toddlers (<3 years)
 - Bleeding diathesis
 - Patients with massive neck edema or lack of landmarks
 - Acute laryngeal disease

Equipment

- Sanders handheld high-pressure ventilator
- 12/14-gauge Jelco IV catheter on a syringe
- Optional: wire-reinforced needle-catheter (e.g., Cook Critical Care)
- Alternatively: ENK oxygen modulator system by Cook Critical Care (low-pressure choice). Requires 15 L/min oxygen supply. Oxygen delivery is derived by finger occlusion of the portals on the plastic assembly. Delivered in similar ratio as high-pressure transtracheal jet ventilation (TTJV). Newer products are being developed that allow more accurate pressure delivery and air egress in the hopes of improving oxygenation, reducing barotrauma, and improving patient safety.

ANATOMY

The thyroid cartilage consists of two approximately quadrilateral-shaped laminae of hyaline cartilage that fuse anteriorly to form the laryngeal prominence. The anterior superior edge of the thyroid cartilage, the laryngeal prominence, is known as the *Adam's apple* and is usually easily seen in men. It is probably the most important landmark in the neck when performing a cricothyrotomy. The cricoid cartilage is shaped like a signet ring with the shield located posteriorly and forms the inferior border of the cricothyroid membrane. The thyroid cartilage forms the superior border of the cricothyroid membrane.

The cricothyroid membrane is a dense fibroelastic membrane located between the thyroid cartilage superiorly and the cricoid cartilage inferiorly; the cricothyroid muscles bound it laterally. The cricothyroid membrane covers an area that is trapezoidal in shape. The average size of the cricothyroid membrane in the adult is approximately 22 to 30 mm wide and 9 to 10 mm high. Palpating a notch, a slight indentation or dip in the skin inferior to the laryngeal prominence, can identify the cricothyroid membrane. The cricothyroid membrane is located approximately 2 to 3 cm below the laryngeal prominence in an adult.

PROCEDURE

- Place the patient in supine position (shoulder roll to extend cervical spine forward if possible).
- Prep neck area if time permits.
- Locate cricothyroid membrane.
- Using a 12- or 14-gauge needle on a syringe, puncture the skin midline and directly over the cricothyroid membrane. (2-3 mL saline in 5- or 10-mL syringe will assist visualizing bubbles).

*Relative contraindications may be overlooked in the true emergency situation, because it is more important to obtain an airway and avoid hypoxemia.

- Direct the needle at a 45-degree angle caudally, and carefully insert it through the upper half of the cricothyroid membrane, aspirating as the needle is advanced. Aspiration of air signifies entry into the tracheal lumen.
- Secure the needle (assign one person to maintain catheter position), and attach Luer-Lok end of high-pressure ventilator.
- Administer low-pressure airflow (5-10 psi initially) bursts of positive-pressure ventilation.
- 6-10 breaths per minute to maximize exhalation time (I/E ratio > 1:5)
- Adjust pressure upward with the goal of visible chest wall excursions and life-sustaining saturation.
- Continue efforts to maintain airway patency to ensure egress of pressurized air (exhalation)
 - Jaw thrust, chin lift, neck extension
 - Oral airway, nasal airway, tongue retraction
 - SGA device, laryngoscopy
- TTJV is short-term oxygen delivery strategy during airway management difficulties.
 - Alternative airway management methods should be pursued.
 - Continue efforts to secure the airway from above if feasible.
 - Pressurization of airway may allow previously failed rescue methods to succeed—i.e., drive airway upward through the glottis, thus revealing an otherwise collapsed, edematous, or unrecognizable airway.
- NOTE: Placing catheter via cricothyroid membrane prior to airway intervention (anticipating difficulty) is acceptable, since placement during a crisis is often hindered by lack of landmarks, suboptimal positioning, and inexperience. If placed but not used, it can be simply removed with little consequence.

AFTER PROCEDURE

Postprocedure Care

- TTJV is considered a short-term “fix” to supplement oxygenation in a life-saving fashion; ventilation (CO₂ exchange) may be limited.
- Continued efforts to secure the airway with advanced techniques (FFB, VAL, SGA) should be pursued.
- Creation of a surgical airway (tracheostomy) is possible with active TTJV taking place.
- Removal of the catheter is quick and with little consequence.

Complications

- Common
 - Kinking of the catheter (use wire-reinforced catheter)
 - Blockage or obstruction of the catheter (redirect or withdraw slightly)
- Infrequent
 - Subcutaneous emphysema of neck, thorax, face
 - Minor bleeding
 - Infection (rare)
 - Incorrect or unsuccessful catheter placement
- Serious, rare complications
 - Damage to the laryngeal cartilage
 - Serious hemorrhage due to severed blood vessel
 - Posterior wall perforation (concerning), but if followed by TTJV, devastating consequences may take place
 - Pressurization of intratracheal airway leading to barotrauma, pneumothorax or worse, tension pneumothorax, pneumomediastinum, pneumopericardium

OUTCOMES AND EVIDENCE

- Patient outcomes after TTJV are related to their coexisting condition

- Recognized as life-saving maneuver in many airway management algorithms
- Lack of training, lack of practice, low frequency of performing procedure make it high risk
- Successful catheter placement may be fraught with incorrect I:E ratio, excessive delivery of breaths (>12/min), lack of pressure egress
- Owing to the emergency nature of the procedure, randomized controlled studies in humans are not possible in the emergency setting.
- Technique used successfully in elective setting with proper equipment, trained and knowledgeable personnel performing TTJV

NEEDLE AND SURGICAL CRICOTHYROTOMY: BEFORE PROCEDURE

Indications

- Impossible or failed oral or nasal endotracheal intubation due to any of the following
 - Very difficult/impossible intubation (ventilation/oxygenation possible)
 - CVCI airway
 - Massive oral, nasal, or pharyngeal hemorrhage
 - Massive regurgitation or emesis
 - Masseter spasm
 - Clenched teeth
 - Structural deformities of oropharynx, congenital or acquired
 - Stenosis of upper airway
 - Laryngospasm
 - Mass (cancer, tumor, polyp, or other)
- Airway obstruction (partial or complete) that cannot be cleared
 - Nontraumatic
 - Oropharyngeal edema
 - Laryngospasm
 - Mass (cancer, tumor, polyp, or other away from insertion site)
 - Traumatic
 - Foreign body obstruction (above level of insertion)
 - Supraglottic, glottic, or subglottic stenosis/narrowing (above insertion site)
- Traumatic injuries making oral or nasal endotracheal intubation difficult or potentially hazardous
 - Maxillofacial injuries
 - Cervical spine instability

- Elective versus urgent versus emergent
 - Elective: critical airway situation noted prior to induction, patient hemodynamically stable, oxygenation/ventilation adequate
 - Urgent: critical airway situation noted prior to or during induction, patient's hemodynamics and/or oxygenation/ventilation compromised
 - Emergent: critical airway situation during induction, patient hemodynamically unstable and/or oxygenation/ventilation deterioration

Contraindications

- Absolute contraindications
 - Endotracheal intubation can be accomplished easily and quickly, and no contraindications to endotracheal intubation are present.
 - Transection of trachea with retraction of distal end into the mediastinum
 - Fracture or other significant injury of the larynx or cricoid cartilage
- Relative contraindications*
 - Infants and toddlers (<3 years)
 - Bleeding diathesis
 - Patients with massive neck edema, lack of landmarks
 - Acute laryngeal disease (mass, tumor, infection over cricothyroid membrane)

Equipment

- Homemade
 - Guide wire
 - #20 scalpel blade
 - 14-, 16-, or 18-gauge cutting needle on a syringe (depending on wire gauge)
 - Cuffed 6.0 ETT on a dilator (with lumen)
 - Optional: cuffed, nonfenestrated, #4 and #5 tracheostomy tubes
 - Scalpel, #11
 - Trousseau dilator
 - Tracheal hook
 - 4 × 4 gauze sponges
 - Optional equipment: 2 small hemostats, surgical drapes, 1% lidocaine with syringe and needle
- Prepackaged (e.g., Melker Cricothyrotomy, Cook Critical Care) (Fig. E1-26)

ANATOMY

The thyroid cartilage consists of two approximately quadrilateral-shaped laminae of hyaline cartilage that fuse anteriorly to form the laryngeal prominence. The anterior superior edge of the thyroid cartilage, the laryngeal prominence, is known as the *Adam's apple* and is usually easily seen in men. It is probably the most important landmark in the neck when performing a cricothyrotomy. The cricoid cartilage is shaped like a signet ring with the shield located posteriorly and forms the inferior border of the cricothyroid membrane. The thyroid cartilage forms the superior border of the cricothyroid membrane (Fig. E1-27).

The cricothyroid membrane is a dense fibroelastic membrane located between the thyroid cartilage superiorly and the cricoid cartilage inferiorly; the cricothyroid muscles bound it laterally. The cricothyroid membrane covers an area that is trapezoidal in shape. The average size of the cricothyroid membrane in the adult is approximately 22 to 30 mm wide and 9 to 10 mm high. Palpating a notch, a slight indentation or dip in the skin inferior to the laryngeal prominence, can

*Relative contraindications may be overlooked in the true emergency situation, because it is more important to obtain an airway and avoid hypoxemia.

FIGURE E1-26 ■ Prepackaged surgical kit.

FIGURE E1-27 ■ Anatomic outline shows the sternal notch (lower "V"), the straight line (cricoid ring), and the two curved arrows that overlie the cricothyroid membrane, with the outline of the thyroid cartilage above the cricothyroid membrane.

identify the cricothyroid membrane. The cricothyroid membrane is located approximately 2 to 3 cm below the laryngeal prominence in an adult.

PROCEDURE: CONVENTIONAL APPROACH

- Place the patient in a supine position, hyperextended neck with shoulder roll if possible.
- Surgically prep the area using antiseptic solution (if applicable, time permitting).
- Palpate the cricothyroid membrane anteriorly, between the thyroid cartilage and cricoid cartilage.
- Immobilize the larynx—in the right-handed operator, the thumb and long fingers of the left hand are used to grasp the thyroid cartilage.
- Incise the skin—vertical and midline, approximately 2 to 3 cm in length from the depth of the thyroid cartilage, membrane, and cricoid cartilage.
- Prepare subcutaneous tissue—dissect down to the cricothyroid membrane.
- Incise the membrane—transverse, midline, and at least 1.5 cm long to facilitate ETT placement.

- Place tracheal hook on lower edge of thyroid cartilage and lift upward and cephalad.
- Alternatively, place tracheal hook on upper edge of cricoid ring and lift upward and caudad.
- Place ETT or tracheostomy tube—smaller diameter preferred (5.0 to 6.5 mm)
- Inflate cuff and confirm placement using auscultation and/or capnography.
- Secure the tube.
- Optional: FFB evaluation

■ PROCEDURE: STYLET-DILATOR METHOD

- Place the patient in a supine position, hyperextended neck with shoulder roll if possible.
- Surgically prep the area using antiseptic solution (if applicable, time permitting).
- Palpate the cricothyroid membrane anteriorly, between the thyroid cartilage and cricoid cartilage.
- Using a 14-gauge needle on a syringe, puncture the skin midline and directly over the cricothyroid membrane.
- Direct the needle at a 45-degree angle caudally, and carefully insert it through the upper half of the cricothyroid membrane, aspirating as the needle is advanced. Aspiration of air signifies entry into the tracheal lumen.
- Secure the needle, and advance the flexible end of the wire first.
- Once a sufficient amount of the wire is introduced into the trachea, remove the needle.
- Using a 20-blade scalpel, make a deep horizontal puncture.
- Insert the dilator and endotracheal tube assembly onto the wire, and gently advance through the cricothyroid membrane with a continuous downward twisting motion.
- Remove the dilator, inflate the endotracheal cuff, and connect the breathing circuit.
- Secure ETT, auscultate breath sounds, and confirm the return of CO₂.
- Optional: FFB evaluation of airway

■ PROCEDURE: SELDINGER TECHNIQUE—MELKER COOK CRITICAL CARE

- Supine position, hyperextended neck with shoulder roll if possible
- Surgically prep the area using antiseptic solution (if applicable, time permitting).
- Palpate the cricothyroid membrane anteriorly, between the thyroid cartilage and cricoid cartilage.
- Immobilize larynx as described earlier.
- Puncture the skin and the cricothyroid membrane with the puncture cannula with connected syringe.
- Aspiration of air confirms entry into trachea with needle directed caudad.
- Disconnect syringe from needle, pass the wire caudad into airway, remove needle.
- Incise skin 0.5 to 1 cm on each side of the wire guide.
- Insert the dilator together with deflated airway catheter over the wire, through the skin, into the trachea.
- Remove dilator, inflate cuff, and confirm correct tube placement.
- Secure ETT, auscultate breath sounds, and confirm the return of CO₂.
- Optional: FFB evaluation of airway

■ PROCEDURE: SURGICAL APPROACH—RAPID FOUR-STEP OR MODIFIED THREE-STEP

- Supine position, hyperextended neck with shoulder roll if possible
- Surgically prep the area using antiseptic solution (if applicable, time permitting).

- Palpate the cricothyroid membrane anteriorly, between the thyroid cartilage and cricoid cartilage.
- Immobilize larynx as described earlier.
- Incise skin and cricothyroid membrane transversely with scalpel blade.
- Insert a tracheal hook through the incision; secure the cricoid cartilage with the hook.
- Move to a more ventral and caudal position (outward and downward direction with hook).
- Insert smaller-diameter ETT into opening of trachea.
- Three-step technique
 - Midline incision into the skin followed by horizontal division of cricothyroid membrane
 - Advancement of elastic bougie through tracheal space into right mainstem bronchus
 - Advancement of ETT over bougie, removal of bougie
 - Secure ETT, auscultate breath sounds, and confirm the return of CO₂.

■ AFTER PROCEDURE

Postprocedure Care

- Postprocedure care should include the insertion of an orogastric or nasogastric tube in cases of full stomach.
- Revision of the cricothyrotomy may be needed as soon as the patient is stable.
- Most cases have previous laryngeal damage or postobstruction pulmonary edema and will require ventilation in the ICU.

Complications

- Common
 - Kinking of the catheter, wire
 - Blockage or obstruction of the catheter
- Infrequent (potentially life-threatening)
 - Kinking of the catheter
 - Aspiration
 - Creation of false passage into the tissue
 - Subglottic stenosis
 - Laryngeal stenosis
 - Hemorrhage/hematoma
 - Esophageal/tracheal laceration
 - Mediastinal emphysema
 - Vocal cord injury
 - Minor bleeding
 - Infection
 - Incorrect or unsuccessful catheter placement
- Serious rare complications
 - Damage to the laryngeal cartilage
 - Serious hemorrhage due to severed blood vessel
 - False passage, loss of airway
 - Pneumothorax, tension component

■ OUTCOMES AND EVIDENCE

- Patient outcomes after needle cricothyrotomy are related to coexisting conditions.
 - Lowest survival rates are associated with cricothyrotomy undertaken during cardiac arrest (only 6%), compared to 76% for any other reason.
- Most common causes of death are patient comorbidities, followed by failure to achieve an airway, and last, by the procedure itself.
- Owing to the emergency nature of the procedure, randomized controlled studies in humans are not likely to be performed.
- Because cricothyroidotomy is a rarely performed but potentially life-saving procedure of last resort in the patient with a failed airway, clinicians responsible for airway management must retain familiarity with the necessary equipment and relevant anatomy.

- Clinicians responsible for advanced airway management should review the anatomy and practice with the equipment needed for cricothyroidotomy several times per year.
- At the very least, clinicians should know who to call for assistance with gaining surgical access to the airway.
- Immediate access to needed equipment is imperative to optimize patient safety.
- Delay in starting surgical access, lack of equipment, and inexperience with the technique are the most common underlying reasons for poor outcome.
- While an emergency surgical airway may be glamorized to be done rapidly, given common anatomic and positioning restraints (cervical collar, CPR, ongoing BVM, poor positioning, obese thick neck devoid of landmarks), it is the exception that it can be performed accurately in less than 45 seconds. Clinical experience suggests >1 to 3 minutes and well beyond this time frame in many instances.

ESOPHAGEAL-TRACHEAL COMBITUBE: ALTERNATIVELY, THE RUSCH EASY TUBE (SMALLER—LATEX FREE COMBITUBE LOOK ALIKE AND THE KING LT-LARYNGEAL TUBE-SINGLE LUMEN, ESOPHAGEAL PLACEMENT, ONE SYRINGE FOR DUAL CUFF INFLATION): BEFORE PROCEDURE

Indications

- Emergency airway device in the CVCI pathway
 - Provides rapid control of airway when intubation is impossible and other techniques of securing the airway fail
- Airway management when the patient situation disallows laryngoscopy or bag-mask ventilation due to positioning, confinement
 - Example: trapped in a car after motor vehicle crash and inability to perform laryngoscopy

Contraindications

- Absolute
 - Pediatrics or patients less than 4 feet tall
 - Pediatric sizes unavailable
 - Airway obstruction (supraglottic and below)

- Intact gag reflex
- Recent upper esophageal surgery (i.e., Ivor Lewis esophagogastricectomy)
- Caustic ingestion
- Latex allergy
 - Combitube includes latex in its construction
 - Alternative product: EasyTube, Rusch Medical (latex free); similar in design to Combitube
- Relative
 - Elective/nonemergent situations
 - Example: easy intubation, easy bag-mask ventilation
 - Esophageal pathology (proximal third, upper portion)
 - Example: patient with known esophageal varices; however, if patient is hypoxic and no other airway is possible, benefits clearly outweigh risks. Variceal location tends to be in the lower half of the esophagus.
 - Anatomic alteration of supraglottic area, glottis, hypopharynx
 - Tumor, abscess, foreign body, swelling
 - Emergency short-term use for airway rescue is acceptable.
 - King laryngeal tube
 - Responsive patients with an intact gag reflex
 - Patients with known esophageal disease
 - Patients who have ingested caustic substances

Equipment

- The Esophageal-Tracheal Combitube (Kendall-Sheridan, Argyle, New York) is available in two sizes, 41F (large adult) and 37F. It is a double-lumen soft plastic tube that is inserted into the mouth with or without laryngoscopy and advanced blindly into either the trachea or esophagus (>90% pass into the esophagus). The Combitube has two inflatable cuffs: a smaller distal cuff similar to that of a conventional endotracheal tube and a larger proximal cuff designed to seal the pharynx. Once placed, the practitioner must ventilate the proper conduit to deliver oxygen into the trachea. Understanding the Combitube's design is imperative to its successful use and fosters the ability to troubleshoot difficulties. The Combitube is joined by its recently introduced cousins, the Rusch EasyTube and King laryngeal tube (LT). The Rusch EasyTube is a latex-free alternative that is offered in a large model (similar to the Combitube 41F) and a smaller adult version (35F). The Combitube enters the esophagus in over 95% of cases; ventilation is through lumen #1 (blue connector). End-tidal CO₂ detection, pulse oximetry, and other confirmatory measures must be confirmed for all placements. The occasional placement in the trachea requires ventilation of the lungs through lumen #2 (Fig. E1-28).
- Another airway device that is gaining popularity for in-hospital and prehospital use is the King LT, which is blindly inserted into the hypopharynx with the distal tip inserted past the

FIGURE E1-28 ■ King laryngeal tube (LT) (upper) and Combitube (lower) are both dual-balloon airway devices. Combitube has a long track record of excellent performance but is being challenged by the smaller sized King laryngeal tube, with its single pilot valve/dual cuff design and single ventilation portal.

FIGURE E1-29 ■ Combitube in the esophageal position with both balloons inflated. Proper positioning of the eight side ventilation portals allow oxygen delivery into the glottis. If resistance is met when bagging, it is typically caused by two factors: (1) Combitube is positioned too deep, so some or all of the ventilation portals are occluded by esophageal mucosa (solution: withdraw Combitube to a more proximal position); (2) upper inflated cuff has forced the epiglottis downward and is partially or completely obstructing the glottic opening (solution: withdraw Combitube to a more proximal position).

cricopharyngeal opening of the esophagus (not in the trachea). The ventilation portal comes to rest posterior and inferior to the epiglottis in proximity to the open glottis. It has two high-volume low-pressure inflatable balloons similar to the Combitube (one that occludes the esophagus and one that inflates in the posterior oropharynx) yet requires fewer steps, because it is reliant on only a single site of inflation. The distal cuff is designed to seal the esophagus. The proximal cuff is intended to seal the oropharynx. Ventilation is achieved via a 15-mm connector (single portal as opposed to the Combitube's two) for attachment to a standard breathing circuit or resuscitation bag. The patient may breathe spontaneously via the King LT. CO₂ detection is adaptable to all three devices (Fig. E1-29).

ANATOMY

An understanding of basic airway, tracheal, and esophageal anatomy is required to interpret which lumen should be used to ventilate the patient. Also, if ventilation is unsuccessful, it is important to understand that the positioning of the Combitube may not be ideal, and it may have to be advanced or withdrawn slightly.

PROCEDURE: COMBITUBE

- The Combitube is an emergency airway management device for patients requiring rapid control of the airway, particularly when poor laryngoscopic visualization of the larynx makes tracheal intubation impossible.
- Insert appropriate-sized Combitube into patient's mouth, with or without laryngoscopy (the smaller-sized Combitube [37F] may be used in all adults <6 feet, 5 inches tall).
- Advance the Combitube blindly into either the trachea or esophagus.
- Stop advancing once the proximal depth indicator (two black rings) is at the level of the teeth.
- Inflate the smaller distal cuff and the larger proximal cuff that seals the pharynx.
- Ventilate through the proximal (blue, #1) lumen first, because 95% of Combitube placements result in an esophageal position and auscultate the lungs and stomach.

- If breath sounds are not heard but gastric sounds are, the Combitube has likely been placed in the trachea.
- Simply change ventilation to the distal (clear, #2) lumen, and recheck for breath sounds.
- If breath sounds are still not detectable by auscultation, the Combitube has likely been advanced too deeply into the esophagus, and the pharyngeal cuff is obstructing the glottis.
- If this occurs, deflate the pharyngeal cuff, withdraw the Combitube a few centimeters, and recheck for breath sounds.
- Once the appropriate lumen has been selected and ventilation appears adequate, confirm with capnography.

PROCEDURE: KING LARYNGEAL TUBE

The King LT is a supraglottic airway that uses two cuffs to create a supraglottic ventilation seal similar to the Combitube (hypopharynx and esophageal level). The King LT has a single ventilation port (15-mm connector) and a single valve and pilot balloon that simultaneously inflate both the pharyngeal and the esophageal balloons.

- Assuming the operator is familiar with the King LT, lubrication is applied and preoxygenation is completed.
- Sniffing position if possible but not required.
- Hold the King LT at the connector with dominant hand. With nondominant hand, hold mouth open and apply chin lift.
- With the King LT rotated laterally 45 to 90 degrees such that the blue orientation line is touching the corner of the mouth, introduce tip into mouth and advance behind base of tongue.
- As tube tip passes under tongue, rotate tube back to midline (blue orientation line faces chin).
- Without exerting excessive force, advance tube until base of connector is aligned with teeth or gums.
- Inflate via the single pilot valve until sealed (40-80 mL, depending on King LT size).
- Gently ventilate to assess position (free-flowing I/E, large V_T).
- Depth markings give an indication of the distance from the vocal cords to the teeth.
- Confirm proper position by auscultation, chest movement, and verification of CO₂.
- If ventilation is met with high resistance, slowly withdraw device until ventilation improves.
- Intubation may be accomplished with the FFB-Aintree combination (Figs. E1-30 and E1-31).
- The Rusch EasyTube is another alternative to these two products. It is available in two sizes; 41F and 28F, has a single lumen at the distal end, two separate cuffs for inflation as does the Combitube and a latex-free balloon and offers access to the upper airway (via a suction catheter, airway exchange catheter, or flexible bronchoscopy).

AFTER PROCEDURE

Postprocedure Care

- Once patient is stabilized and adequately ventilated and oxygenated, a more definitive airway should be secured.
 - It is an acute emergency airway device.
 - The three products are not intended for extended use in the emergency patient.
 - Intubation of the trachea is favored in most patients, so a plan should be developed to change to an ETT.
 - Changing to an ETT may be performed with the use of conventional and advanced airway devices.
 - If exchange is considered to be dangerous and risky (desaturation, massive edema, poor pulmonary compliance) or it proves to be impossible to identify the glottic opening, securing the airway surgically may be the best (or only) alternative.
 - When the three devices are in the esophageal position, surgical entrance into the trachea is not impeded by the airway device.

FIGURE E1-30 ■ Close-up view of King laryngeal tube and the ventilation holes that come to lie posterior to the glottic opening. The upper opening will emit an FFB or FFB-Aintree combo to visualize/intubate the trachea. (With permission from Ambu, Inc., Glen Burnie, Maryland.)

Complications

- Common
 - Difficulty maintaining a cuff seal to provide adequate positive-pressure ventilation
 - Regurgitation and aspiration would ideally be limited, but complete protection is not guaranteed.
- Serious, rare complications
 - Lacerations to the esophageal wall or pyriform sinus
 - Can result in subcutaneous emphysema, pneumomediastinum, pneumoperitoneum, and esophageal rupture
 - Ischemia of tongue/airway edema if left in place for long duration

OUTCOMES AND EVIDENCE

These devices, though relatively simple and timely to place, do require complete familiarization with their placement, cuff inflation features, and limitations. The King LT is popular as an elective airway support device as well as a useful rescue airway device in cases of an unexpectedly difficult airway. Anecdotally, clinicians may prefer the King LT based on its smaller size and simplicity with one inflation portal.

FIGURE E1-31 ■ **A**, The Cook brand Aintree catheter acts as a “jacket” around the flexible fiberoptic bronchoscope (FFB), which is then passed (in this case) via the laryngeal mask airway to assist in visualizing the glottic opening. The Aintree-FFB combo can be passed via the ventilation portal of the King laryngeal tube (LT) to allow passage into the trachea. Following removal of the FFB from the Aintree (which remains in the trachea), the King LT is removed over the Aintree. A lubricated endotracheal tube (ETT) is then passed over the Aintree, as it acts as a bougie. **B**, The Aintree catheter, a 56-cm-long, hollow catheter.

EVALUATION OF A CUFF LEAK IN THE ICU: BEFORE PROCEDURE

Indications

- Audible cuff leak in an intubated patient may represent a variety of problems
 - Tear/microperforation or macroperforation of ETT cuff
 - Remedy: exchange ETT

FIGURE E1-32 ■ Commercially available pilot balloon repair kit. Blunt needle is inserted into the cut end of the pilot valve line.

FIGURE E1-33 ■ This patient had a continuous “cuff leak” while supported on mechanical ventilation. The endotracheal tube (ETT) depth was 25 cm at the dentition, yet the ETT tip is just below the vocal cords when viewed with the FFB. The barely visible white vocal cords are “stretched” by the ETT and are located laterally in the picture. In the upper right corner is the bluish edge of the lower portion of the ETT cuff. Distally at the ETT, one can see with the FFB that the posterior wall of the thyroid cartilage is visible (not seen in this picture).

- Broken pilot balloon line
 - Remedy: occlude line perforation, inflate cuff, clamp line with Kelly/hemostat (temporary, low risk)
 - Remedy: cut line, attach new pilot balloon/valve/line assembly, reinflate balloon (less temporary, may perform well long term, low risk)
 - Change ETT (high risk) (Fig. E1-32).
- Incompetent valve/pilot balloon perforation/dysfunction
 - Remedy: cut line, attach new pilot balloon/valve/line assembly, reinflate balloon (less temporary, may perform well long term, low risk)
 - Remedy: inflate cuff, clamp line with Kelly/hemostat (temporary)
 - Remedy: change ETT (high risk)
- ETT cuff/tracheal wall incongruity (tracheomalacia, tracheal softening, tracheitis, overstretched poorly compliant cuff)
 - Remedy: advance ETT/cuff to alternative level in trachea (temporary, low risk)
 - Remedy: change ETT (high risk) or change tracheostomy to larger size, length, or cuff shape/design (moderate or high risk if trach >10 days old)
- Dislocation of ETT (partial or complete extubation of the trachea) is typified by three potential locations within the airway
 - Cuff between vocal cords (partial extubation)
 - ETT tip at level of vocal cords (complete extubation)
 - ETT tip/cuff in hypopharynx (complete extubation) (Figs. E1-33 through E1-35)
- Partial/complete extubation of the airway, masquerading as an ETT with a cuff leak, must be identified
 - It is imperative to check the status of the pilot balloon.
 - If the pilot balloon appears to be intact (holds insufflated air), the ETT tip/cuff location is likely not intratracheal.
 - If the “cuff” leak is erroneously identified as a malfunctioning ETT cuff, and the airway team passes an airway exchange catheter (AEC), the misplaced distal tip of the ETT may allow passage of the AEC to areas external to the trachea (e.g., esophagus, pyriform sinus)

FIGURE E1-34 ■ The ICU physician was called to evaluate an intermittent “cuff leak,” difficulty passing the suction catheter, and waxing/waning oxygen saturation. The pilot balloon was intact and inflated. Flexible fiberoptic bronchoscopic exam found the endotracheal tube (ETT) tip was impaled on the vocal cord, with a view of the subglottic area via the Murphy eye of the ETT. The FFB was passed into the trachea via the Murphy eye, and the ETT was gently advanced into the trachea.

- Two methods are strongly recommended to diagnostically and therapeutically manage the possible ETT tip/cuff dislocation
 - First choice: FFB to diagnose the tip location and therapeutically allow reintubation of the trachea if possible (85% likely at authors’ institution)
 - Second choice: laryngoscopy, preferably VAL versus direct laryngoscopy (DL), so as to allow improved visualization of the airway and possibly improve the margin of safety in this

FIGURE E1-35 ■ The intensive care unit team was called to investigate a continuous “cuff leak” in this patient. The pilot balloon was intact; the fiberoptic bronchoscopic (FFB) view of the vocal cords from the tip of the endotracheal tube (ETT) reveals that the ETT tip is well above the glottic opening. The FFB was advanced into the trachea, and the ETT was then returned to the tracheal position.

potentially life-threatening consequence of the intubated ICU patient

- **Caveat:** How reliable is the level of the ETT at the dentition line in determining where the tip is located (based on a database of 245 cases of partial extubation at the authors' institution)?
 - ETT at <20 cm at the dentition line: 55% were above the glottis
 - ETT at >20 cm: 73% at level of glottis or above glottis (hypopharynx)
- **Conclusion:** There appears to be little correlation of ETT markings at the dentition line and the location of the ETT tip.
- Overall, 51% ETT tips were above the vocal cords, 32% were at the level of the vocal cords, and in 17%, the cuff was located between the vocal cords on examination.
- **Caveat:** Is there any difference in the incidence of complications when using FFB versus DL to diagnose and manage a dislocated ETT?
 - Managing this clinical situation with DL alone was fraught with complications such as severe hypoxemia, esophageal intubation, loss of the airway, bradycardia, and cardiac arrest.
 - Diagnostic and therapeutic management with FFB was an overall excellent choice, but it was not without its own problems. The ETT tip that was above the vocal cords was often centralized and easily advanced into the trachea, but approximately 15% to 20% of these cases had the ETT tip abutting the vocal cords, pharyngeal wall, or other tissues that made it very difficult to advance the FFB into the trachea. Several of these ETTs had to be moved more proximal to allow FFB advancement, but this was not always successful.
 - Alternative airway management schema beyond the FFB must be available to rescue the airway in the event difficulty is encountered.

Contraindications

- Absolute
 - Difficult intubation and ETT can be salvaged by some other means than replacing it (e.g., repair of pilot balloon or clearing

FIGURE E1-36 ■ This patient immediately failed a continuous positive airway pressure (CPAP) trial. Investigation with fiberoptic bronchoscopy (FFB) found significant biofilm accumulation at several levels of the endotracheal tube (ETT) lumen. A choice of exchanging to a new ETT was contemplated, but the patient was a known difficult airway. A catheter with an inflatable cuff (similar to a Fogarty catheter) that had a mesh covering for “traction” was passed and was able to remove 90% of biofilm blockage in less than 90 seconds on two passes.

FIGURE E1-37 ■ The same endotracheal tube (ETT) as in Fig. E1-36, following a single pass of the biofilm removal catheter.

of obstructive luminal secretions via the CAM Resqu-Cath) (Figs. E1-36 through E1-38).

- Relative
 - Unprepared
 - Unless the situation is truly emergent, ETT exchange should not be attempted without properly preparing the patient and without having immediate access to difficult airway supplies.
 - ETT is not damaged
 - If the reason for exchange is for “cuff leak,” for example, but the leak is due to supraglottic positioning, not a damaged cuff, then adjustment of the ETT and not ETT exchange is appropriate. However, an overdistended ETT cuff may suffer

FIGURE E1-38 ■ **A**, A large biofilm plug removed following a single pass of the biofilm removal system. **B**, Close-up of the mesh-covered catheter cuff used to remove the tracheal lumen obstruction of biofilm.

from altered compliance due to stretching. Thus, a new ETT may be advantageous.

Equipment

- Conventional intubation equipment
- Advanced airway rescue devices including FFB, VAL
- Miscellaneous equipment
 - Kelly clamp/hemostat
 - Replacement pilot balloon kit

PROCEDURE

- Place patient on 100% oxygen.
- Review patient history, problem list, medications, level of ventilatory support.
- Assemble conventional and rescue airway equipment including capnography.
- Initiate sedation/analgesia if not already present, with or without muscle paralysis
- Optimize positioning, perform FFB to determine level of the ETT tip if appropriate, and then advance the ETT over the FFB into the trachea.
 - Alternative rescue methods, personnel should be immediately available
- Second choice: examination of the airway (laryngoscopy, video-based preferable)
 - Extra caution when advancing laryngoscope blade into oropharynx, as the tip may puncture the overinflated ETT cuff in the “back” of the throat.
- Consideration should be given to replacing the ETT when its cuff has undergone overinflation and may have altered compliance.

AFTER PROCEDURE

Postprocedure Care

- Reconfirm endotracheal placement with capnography.
- Assess depth of ETT with breath-sound auscultation, bronchoscopy, chest radiograph (delayed).

Complications

- Common
 - Inability to advance new ETT owing to tip imbedded in the upper airway tissues
 - Hypoxemia
- Serious rare complications
 - Loss of difficult airway
 - Most feared and worst outcome
 - Can be reduced by using FFB versus DL
 - Use VAL over DL
 - Ensure airway team has adequate supportive staff and immediate access to advanced airway equipment (including surgical staff)

OUTCOMES AND EVIDENCE

Partial extubation of the airway can be a life-threatening consequence of tracheal intubation in the ICU patient. Misdiagnosis or lack of understanding of this situation may lead to patient morbidity and mortality. Being prepared, as is the case for any ICU airway situation, is in the best interest of patient safety. Running through the differential diagnosis of a “cuff leak” is imperative. The simplest task to complete is to inquire about the characteristics of the cuff leak (duration, amount of air placed in cuff, etc.) and to check its integrity. If the pilot balloon appears intact, it is reasonable to assume the ETT tip cuff is displaced at or above the vocal cords and one should consider FFB for diagnostic and therapeutic management. Again, VAL is invaluable as both a diagnostic and therapeutic option.

EXTUBATION OF THE DIFFICULT AIRWAY: BEFORE PROCEDURE

Indications

- To optimize the safety of the ICU patient being readied for extubation, with special emphasis on the difficult airway patient
- Known difficult airway
 - Known difficult mask ventilation
 - Known difficult laryngoscopy
 - Known difficult intubation
- Suspected difficult airway
 - Obesity
 - Cervical spine precautions, hard collar, halo vest, limited range of motion
 - Edema, swelling, airway trauma, systemic reaction (sepsis, blood transfusion reaction, anaphylaxis)
 - Massive volume resuscitation

- Evolving head/neck trauma, pathology, injury
- Any limitation to the mouth/oral cavity/oropharynx
- Excessive secretions, bleeding, bandages, alterations to anatomy
- *Difficult extubation* is defined as the clinical situation when a patient presents with known or presumed risk factors that may contribute to difficulty reestablishing access to the airway.
 - The subsequent intolerance of the extubated state poses an increased risk to patient safety.
 - An extubation strategy should be developed that allows the airway manager to (1) replace the ETT in a timely manner and (2) ventilate and oxygenate the patient while the patient is being prepared for reintubation, as well as during the reintubation itself.
 - The practitioner should assess the patient's risk on two levels: the patient's predicted ability to tolerate the extubated state and ability (or inability) to reestablish the airway if reintubation becomes necessary. Weaning criteria and extubation parameters will not be discussed because they vary by locale, practitioner, and the patient's clinical situation.

Contraindications

- Absolute contraindications
 - When the clinical assessment of the patient is suggestive of a high risk for difficulty establishing an airway, and airway management personnel with an expertise of handling such a patient are not present or they are not properly equipped to handle such a patient
 - Patient fails routine accepted extubation parameters for your facility
 - When the full complement of ICU personnel are unavailable for the extubation trial (e.g., nursing staff, respiratory therapy staff, airway team members)
 - When a backup plan/strategy has not been developed or the equipment/personnel to execute such a strategy are not available
- Relative contraindications*
 - Establishing a surgical airway (tracheostomy) would be a better choice.
 - Delaying the extubation trial would be in the patient's best interest.

Equipment

- Conventional airway management equipment
- Advanced airway rescue equipment (difficult airway cart/bag)
 - FFB
 - Advanced VAL equipment
 - Airway exchange catheters
- Nursing staff
- Respiratory therapy staff
- Surgical assistance for a surgical airway (if indicated)
- Sedation/analgesia/muscle relaxant medications
- Postextubation oxygen delivery system
 - Nasal cannula
 - Face mask
 - CPAP, BiPap

ANATOMY

- Patient assessment must be completed prior to decision whether or not to extubate.

- Review of the patient's stay in the ICU, medications, problem list, surgeries, procedures, previous airway interventions, and current clinical condition would be standard to provide needed information to develop an understanding of the patient's current predicament.
- This evaluation would be supported by a clinical assessment of the patient's airway to evaluate inability to tolerate extubation from such causes as
 - Airway obstruction (partial or complete)
 - Hypoventilation syndromes
 - Hypoxemic respiratory failure
 - Failure of pulmonary toilet
 - Inability to protect airway
- Evaluate for potential difficulty reestablishing the airway
 - Difficult airway
 - Limited access to the airway
 - Inexperienced personnel pertaining to airway skills
 - Airway injury, edema formation
- Risk factors for difficult extubation
 - Known difficult airway
 - Suspected difficult airway based on the following factors
 - Restricted access to airway
 - Cervical collar, halo vest, limited range of motion
 - Head and neck trauma, procedures, or surgery
 - ETT size, duration of intubation
 - Head and neck positioning (e.g., prone vs. supine)
 - Traumatic intubation, self-extubation
 - Patient bucking or coughing
 - Drug or systemic reactions
 - Angioedema
 - Anaphylaxis
 - Sepsis-related syndromes
 - Excessive volume resuscitation
- ASA Practice Guidelines have suggested that a preformulated extubation strategy should include
 - A consideration of the relative merits of "awake" extubation versus extubation before the return of consciousness (more applicable to the operating room setting)
 - An evaluation for general clinical factors that may produce an adverse impact on ventilation after the patient has been extubated
 - The formulation of an airway management plan that can be implemented if the patient is not able to maintain adequate ventilation after extubation
 - A consideration of the short-term use of a device that can serve as a guide to facilitate intubation and/or to facilitate ventilation/oxygenation

PROCEDURE

- Suggested three-step patient assessment
 1. Review history, current conditions, medications, mental status as previously stated.
 2. Assess airway; external evaluation supplemented with internal evaluation
 - Conventional laryngoscopy has limited clinical utility in the ICU patient.
 - VAL allows (in most patients) the ability to "see around the corner," thus providing a view of the periglottic airway to determine if the airway is suitable for extubation; also provides valuable information regarding the ease or difficulty of viewing the airway anatomy in the event reintubation needed following extubation.
 3. Develop strategy for extubation, delay extubation or secure via surgical means; extubation choices include
 - Conventional extubation (directly to oxygen source)
 - Extubation over an airway exchange catheter to maintain airway access

*Based on personal preference, experience, and the patient's clinical condition.

FIGURE E1-39 ■ Laryngoscopic view (GlideScope) of a patient with a known difficult airway who is ready for an extubation trial. The airway was assessed to determine two factors: (1) the ease or difficulty of reintubating the trachea if extubation is poorly tolerated and (2) the status of the periglottic tissues (edema, swelling, and trauma) and whether they are compatible with tolerance of the extubated state. This airway view demonstrated residual edema and swelling, as well as secretion buildup.

- FFB-assisted airway evaluation/extubation
- Transition to LMA until patient is “safe” to lose “airway access” (Fig. E1-39)
- Clinical decision plan for the difficult extubation
 - A variety of methods are available to assist the practitioner to maintain continuous access to the airway following extubation, each with its limitations and restrictions.
 - Though no method guarantees control and the ability to resecure the airway at all times, the LMA offers the ability for fiberoptic-assisted visualization of the supraglottic structures while serving as a ventilating and reintubating conduit but is hampered by a limited time frame.
 - FFB is useful for periglottic assessment following extubation but requires advanced skills and minimal secretions. Moreover, it offers only a brief moment for airway assessment and continuous access to the airway following extubation.
 - Conversely, the AEC allows continuous control of the airway after extubation but without visualization, is well tolerated in the vast majority of patients, and serves as an adjunct for reintubation and oxygen administration. Patient intolerance, accidental dislodgment, and mucosal and tracheobronchial wall injury have been reported but are rare.
 - Carinal irritation may be treated with proximal repositioning, instillation of topical agents to anesthetize the airway, plus explanation and reassurance. Dislodgment may occur because of an uncooperative patient or a poorly secured catheter.
 - Observation in a monitored environment with experienced personnel should be given top priority, as should the immediate availability of difficult airway equipment in the event of extubation intolerance.
- Suggested extubation procedure for the difficult airway patient
 - Acquire advanced airway rescue equipment.
 - Assemble personnel (respiratory therapist, nursing staff, and surgical staff).
 - Prepare circumferential tape to secure the airway catheter after extubation.
 - Discussion with patient/family/airway care team
 - Position patient upright; suction internal and external to ETT.
 - If obese, ramped position recommended
 - Pass lubricated AEC to 23- to 26-cm depth (shorter adults <5 ft tall may require a depth of 20-22 cm).

FIGURE E1-40 ■ Patient on postoperative day 2 following an anterior-posterior 4-level cervical fusion, laminectomy, and discectomy at two levels. She required an “awake” flexible fiberoptic bronchoscopy (FFB) intubation to allow induction of anesthesia. Being a known difficult airway to start with, her airway status only worsened with postoperative swelling and the addition of the halo vest that further restricted cervical movement. She was extubated over an airway catheter but developed rapid deterioration due to stridor, requiring emergency passage of a new endotracheal tube (ETT) over the airway catheter, which was accomplished in less than 20 seconds. A smaller-bore ETT was used (6.0) based on the assumption that airway swelling was the cause of the stridor and a smaller ETT would most likely pass more easily into a swollen airway.

- Remove the ETT while maintaining the AEC in its original position.
- Wipe excess lubrication/secretions from the AEC prior to taping.
- Secure the AEC with tape (circumferential) and mark AEC “airway only.”
- Oxygen: nasal, mask, or humidified oxygen
- Maintain NPO, provide pulmonary toilet.
- Ensure availability of smaller-caliber ETT (6.0) for reintubation if needed.
- Maintain patient in monitored setting with skilled personnel available (Fig. E1-40).
- Clinical judgment and the patient’s cardiopulmonary and other systemic conditions, combined with the airway status, should guide the clinician in establishing a reasonable time period for maintaining a state of “reversible extubation” with the indwelling AEC. [Table E1-1](#) shows a suggested time frame for maintaining the well-tolerated AEC. If significant head/neck and/or laryngeal/periglottic edema precludes extubation, several maneuvers may be implemented to assist in decreasing swelling and edema
 - Raise head of bed as much as tolerated.
 - Maintain even to negative in/out fluid balance.
 - Diurese if volume overloaded (common in ICU).
 - Pretreatment (12-24 hours prior to extubation) with corticosteroids if appropriate (controversial but may reduce postextubation stridor, breathing difficulties, reintubation, and laryngeal edema overall)
- SAFETY NOTICE: administration of oxygen (low flow 1-2 L/min, medium flow 3-6 L/min, or high-pressure “JET” delivery)

TABLE E1-1

Time Frame* for Maintaining the Well-Tolerated Airway Exchange Catheter

| | |
|---|------------|
| Difficult airway only, no respiratory issues or airway swelling | 1-4 hours |
| Difficult airway, no direct respiratory issues, potential for airway swelling | 2-6 hours |
| Difficult airway, cardiopulmonary issues, multiple extubation failures | 2-24 hours |

*Time frame will vary according to patient condition, airway assessment, and tolerance of the presence of the airway exchange catheter.

via the AEC cannot be recommended unless preparing for emergency reintubation (short term only). Without proper egress of insufflated oxygen, even low-flow oxygen may lead to barotrauma leading to life-threatening consequences. Thus, oxygen delivery around, not through the AEC lumen, is recommended.

AFTER PROCEDURE

Postprocedure Care

- Optimize patient positioning, pulmonary toilet, minimize sedation.
- Continuous close observation by trained personnel and immediate access to an experienced airway management team
- Failure to tolerate the extubated state may vary from 2% to 25% of all patients over a variable time line such as 12 to 48 hours.
- The ICU setting is unpredictable. Patients may fail extubation because numerous alterations in the patient's condition can take place unexpectedly (e.g., new-onset dysrhythmia, flash pulmonary edema, acute neurologic changes, systemic reactions).

Complications

- Patient intolerance of AEC (10%)
 - Assure distal tip is not irritating the carina/bronchus.
 - Hand holding, explanation may improve tolerance.
 - Local anesthetic application via AEC
- Infrequent
 - Removing AEC too early and reintubation required later
 - AEC is removed by patient or falls out inadvertently.
 - Inability to reintubate tracheal via AEC (requires alternative strategy)
 - Esophageal intubation if AEC is displaced
- Serious rare complications
 - Possible airway obstruction, loss of airway, laryngospasm, mucosal damage
 - Distal tip of AEC perforated tracheobronchial tree, tip misplacement into the aerodigestive tract
 - Barotrauma due to oxygen insufflation via the AEC

OUTCOMES AND EVIDENCE

The difficult airway patient being readied for extubation warrants a strategy that allows a predictable reintubation in a timely manner, thus, a "reversible extubation." Though regional or national guidelines that outline specific management schema for dealing with this clinical situation are not readily available, this outline offers "safety first" for the patient. Much emphasis is focused on placing the ETT into the trachea, yet the more difficult issue is replacing the ETT in a recently extubated airway, typically under adverse clinical conditions. Patient morbidity and even mortality (i.e., brain injury from anoxia) are real

consequences of extubation of the patient with a difficult airway and should be respected and approached cautiously.

VIDEOLARYNGOSCOPE-ASSISTED INTUBATION: BEFORE PROCEDURE

Indications

Video-Assisted Laryngoscopy (VAL)

- Routine tracheal intubation
- Emergency tracheal intubation
- Rescue of other failed intubation methods
- Viewing airway structures for educational/training purposes
- Exchange of tracheostomy tube
- Evaluation of airway structures for foreign body, trauma, edema, cuff leak
- Extubation evaluation of airway
- Assistance with advancement of TEE probe, feeding tube, nasogastric tube (NGT), esophageal dilator
- Evaluate ETT position in situ
- Types of VAL blades
 - Conventional angle (20°-30°) versus acute angle (60°-70°)
 - Channeled versus nonchanneled
 - Hybrid
- Advantages of VAL versus conventional DL (Figs. E1-41 and E1-42)
 - Full view of laryngeal inlet in majority of cases
 - Typically transforms laryngeal view 1 to 2 grades lower (better view)
 - Grade III view of the larynx with DL (grade III: no cords visible, only epiglottis visible) improves to grade I or II with VAL
 - Grade IV (no view of any airway structure) often improves to grade II (enough to allow ETT advancement)
 - Improved line of sight of naked eye with DL, as operator must peer via the mouth opening around dentition, tongue, and the like; view is often restricted, even more so when the ETT is passed into the airway

FIGURE E1-41 ■ Line of sight with direct laryngoscopy.

FIGURE E1-42 ■ Lines of sight for direct laryngoscopy (DL) versus videolaryngoscopy (VAL). There is approximately 30 degrees between the two methods that accounts for the ability to “see around the corner” when the laryngeal view is restricted with DL. Several manufacturers offer both conventional and acute angle blades. Conventional angle blades afford gaining experience with a “Macintosh” blade combined with the advantage of video assisted visualization.

Contraindications

- Unfamiliar with its use
- Recent tracheobronchial reconstruction?

Equipment

Five basic choices (not all-inclusive of models available, multiple manufacturers) (Figs. E1-43 through E1-50)

- Channeled VAL devices (groove or channel that is preloaded with ETT to assist with its passing)
 - Pentax AWS, AirTraq

FIGURE E1-43 ■ The Airtraq, a portable yet disposable channeled videolaryngoscopy (VAL) device that offers excellent laryngeal viewing, given its relatively inexpensive cost and simple external design. (With permission from Prodol Meditec S.A., Vizcaya, Spain.)

FIGURE E1-44 ■ The Pentax AWS, a portable, reusable channeled videolaryngoscope (VAL) with a disposable (clear) blade that has an adjustable video screen (black portion in photo) that adapts to various patient positions. An endotracheal tube (ETT) is preloaded into the channel of the blade to ease advancement into the larynx.

- Unchanneled VAL devices (must manipulate ETT freehand into trachea)
 - GlideScope, McGrath, Storz C-Mac, Storz DCI Video Laryngoscope
- Acute angle blade assembly (e.g., 60°-70°, GlideScope, McGrath, Storz)
- Normal angle blade assembly (e.g., 20°-35°, GlideScope, McGrath, Storz)
- Hybrid blade (offering both styles)
- Alternatively, video optical stylet (ETT loaded on stylet, video assisted intubation)
 - Shikani, Levitan, Bonfils

FIGURE E1-45 ■ GlideScope AVL shown with video screen and two of several sizes of disposable video baton blades designed for neonatal to large adult. The optional specially shaped stylet that conforms to the blade's extreme 60 allows the operator improved access to advance the endotracheal tube to the laryngeal opening. (With permission from Verathon, Inc., Bothell, Washington.)

FIGURE E1-46 ■ The McGrath portable videolaryngoscope is easily transported and offers excellent video-quality images but on a smaller screen. To ease placement in patients with restricted oral access (e.g., halo vest, large chest/breasts, short neck), the device features a disposable clear blade and an adjustable video arm that can be disarticulated to allow the blade to be placed into the mouth and then reattached to the handle.

- A variety of manufacturers offer models from disposable models (Airtraq-Prodol, about \$75) to reusable models that range from \$1500 (single device) to \$30,000 (well-stocked cart).
- Reusable models typically offer a disposable blade cover or video baton sleeve to speed its reusability between patient encounters.

FIGURE E1-47 ■ The Levitan FPS Scope is an optical stylet that assists the operator with visualization of the airway structures via the eyepiece. Elevation of the mandible-tongue complex with a manual jaw thrust or combining the optical stylet with direct laryngoscopy allows the stylet-endotracheal tube to be passed underneath the epiglottis and into the trachea.

FIGURE E1-48 ■ Combining direct laryngoscopy with the optical stylet to achieve laryngeal visualization.

- Most are easily transportable in an airway cart or bag, attached to an IV pole with wheels.

ANATOMY

Periglottic airway anatomy is typically visualized on a video-based screen, which equates to a much larger view as compared to the restricted view of the operator looking through the patient's mouth. Depending on the VAL device, the quality is excellent overall. Even the disposable model offers good color distinction, reasonable detail, and differentiation of various tissue pathologies. The more expensive models offer excellent quality, color, and detail, and some offer recording capabilities. Secretions, blood, and fogging may impede visualization. Adequate mouth opening is required to allow placement of the

FIGURE E1-49 ■ The view offered by a conventional laryngoscope; limited view of glottis structure owing to dependency of operator's line of sight.

FIGURE E1-50 ■ Same patient as Fig. E1-49 but with videolaryngoscope-assisted view, allowing operator full view of epiglottis, arytenoids, and glottic opening.

blade assembly. Moreover, adequate space between the chest-neck-chin-mouth opening must be present to allow manipulation of the blade into the correct position to view the airway. The McGrath scope offers a disarticulating blade handle that allows placement of the blade followed by attachment of the handle, thus easing its placement in the restricted airway.

■ PROCEDURE

- Because of the variety of devices, the operator must be well versed in the individual device's limitations, indications and contraindications, method of placement, angulation within the oral cavity, video characteristics, and more.
- Because of the bulkiness of VAL's blade, a minimum mouth opening is required to allow device placement into the oral cavity. Further, for the nonchanneled models, adequate space must exist to afford ETT manipulation.
- Use of any of these devices is a four-step process
 - Placement into the oral cavity and advancement into the oro-hypopharynx
 - Optimizing the glottis view
 - Advancing the ETT either via the channel, freehand over a stylet that approximates the curve of the device's blade (nonchanneled), or advancing the ETT-optical stylet assembly to the glottic level and then advancing the ETT into the trachea
 - Smooth and gentle advancement into the mouth is required when manipulating the device, since the operator's attention is

FIGURE E1-51 ■ Videolaryngoscope (VAL) view of a massively swollen airway. No features were discernible via direct laryngoscopy. VAL revealed massive edema but enough detail to allow placement of an endotracheal tube.

typically focused on the “view” and not the patient's dentition or airway tissues.

- Additional caveat for using VAL for airway management (Fig. E1-51)
 - Proper removal of the device to minimize patient injury and avoid extubation
 - Fundamentals of airway management must be practiced, even when use of high-tech equipment is incorporated. VAL may be able to overcome the lack of fundamentals.
 - Proper positioning is an absolute must (e.g., ramping the obese patient)
 - Secretions, vomitus, bleeding impede viewing.
 - Do not use equipment you are not trained to use.
 - Do not try a new technique or device in an emergency (do what you do best).
 - Remove the front of a hard cervical collar (maintain midline stabilization).
 - Secure the head to the bed frame for immobilization with 2-inch tape \pm sandbags; this frees up valuable space that would otherwise be occupied by a colleague trying to maintain a midline position, which could interfere with airway management efforts.
 - If the airway should be secured awake, then do so (FFB, VAL, SGA).
 - Always have a backup plan for any VAL difficulty or failure.
 - VAL is only as good as the person holding it.
 - Do not practice in a cavalier manner just because you have VAL available.
 - The SGA has been displaced by VAL; SGA is an excellent VAL rescue device.
 - Never apply excessive force to the device “to make it fit.”
 - Avoid forcing the advancement of the ETT with VAL (there is no visualization of the ETT until it passes the distally placed video chip).
 - Apply lubrication to the blade as needed, as well as to the ETT, to ease passage.
 - If VAL is your first choice and fails, consider trying DL in some cases.

- An infamous quote regarding the use of VAL: VAL will often make a difficult airway an easy one, but it can make an easy airway a difficult one.
- To review the use of any individual VAL device, please refer to the product's website and review it through educational offerings.
- Review of the technique (which varies with each device) and its indications, contraindications, and limitations is imperative for operator confidence and patient safety.
- Practice on mannequins with proper instruction. Instruction by experienced personnel on the elective, healthy, normal-airway patient is a prerequisite to use in the difficult airway or emergency setting.
- Tip may "bounce."
- 10% to 50% of bougies passed into a grade III airway may enter the esophagus.
 - Grade IIIa: 5% to 12% may enter esophagus
- Tip may be gently advanced farther (28-36 cm) to contact carina/main stem bronchus.
 - Tip hang-up provides tactile feedback during blind passage.
- Decision time: passing the ETT
 - If time permits, generously lubricate the ETT.
 - Smaller sized ETTs pass over the bougie more easily than larger ones.
 - Maintain tongue displacement with laryngoscopy/hand grasp.
 - Pass the ETT, but do not force the advancement (an assistant should grasp the proximal end of the bougie to stabilize it).

AFTER PROCEDURE

Postprocedure Care

- Following advancement of ETT into the trachea and reverifying its position, stabilize the ETT in position, and remove the device.
- Though the video attributes allow observation that the ETT is through the glottis, removing the device may jeopardize its position. Once the device is removed, one is unable to confirm its position without again passing the device. Standard methods of determining the ETT position, such as capnography and chest auscultation, are recommended.

Complications

- Difficulty or failure achieving adequate laryngeal view (2%-10%)
 - Inadequate mouth opening, limited mandibular hinge movement
 - Secretions, blood, vomitus, fogging
 - Power failure (battery, electrical, system failure)
- Difficulty or failure to intubate trachea (2%-10%)
 - Inability to manipulate ETT correctly
 - Operator inexperience
 - Altered/traumatized/edematous/mass/distorted anatomy
 - Unable to pass ETT tip past glottis/cricoid ring: use bougie (through the ETT) for assistance
- Infrequent
 - Tissue injury, airway trauma (palatal or tonsillar pillar wall perforation, pharyngeal wall laceration/perforation)
 - Esophageal placement of ETT
 - Dental damage
- Serious, rare complications
 - Mucosal and tissue laceration/perforation leading to mediastinitis/pharyngeal abscess

OUTCOMES AND EVIDENCE

- The addition of the VAL technology is not new, but the era of lower cost, more accessible models is afoot. DL is now being challenged as a first-line approach to airway management. Whether VAL

replaces DL as the primary method of management is difficult to say, primarily because of economic issues.

- The overall usefulness of video-based visualization of the "easy" airway is questionable except for evaluation and educational purposes. However, its use for the restricted laryngeal view with DL, for the difficult airway (either known or presumed), and for its role as a rescue device for failed DL is without question a welcome addition to our airway arsenal.
- VAL serves a variety of roles in airway management in the ICU setting, well beyond simply tracheal intubation. Extubation evaluation, ETT exchange, rescue of DL failures, plus its use as a primary management choice are but a few.
- The impact VAL imparts on ICU airway management is not currently reflected in the management algorithms offered by anesthesiology societies in the United States, Canada, the United Kingdom, Germany, and many other countries.
- Likewise, its presumed improvement in patient care is intuitive, but it must be proven through research and be evidence-based to warrant its ubiquitous inclusion in ICU airway management as a standard of care. The airway team must use it with caution, practice basic airway fundamentals, and develop a rescue strategy for VAL difficulty or failure, because they will occur regularly, especially in the high-risk ICU patient population.

ETT EXCHANGE: BEFORE PROCEDURE

Indications

Common Reasons in the ICU Setting

- Dysfunctional ETT (cuff, pilot balloon, narrowed lumen, biofilm, obstruction)
- Change location (nasal-to-oral, oral-to-nasal)
- Change size or type of ETT (7.0→8.0, double-lumen to single-lumen ETT)
- Similar clinical circumstances with tracheostomy tube exchange
- ETT exchange has been mentioned under other headings as it pertains to airway management procedures
- Elective versus urgent versus emergent conditions
 - May affect one's ability to accurately evaluate the airway situation
 - Primary reason to have trained personnel and an appropriately stocked difficult airway cart in the ICU setting

- Time permitting, review current patient medical/surgical history, airway procedures
 - Current ventilator settings
 - Current sedatives, analgesics, vasoactive agents
 - ETT secretion status, ETT patency, reason for exchange (clarify request) and substantiate that it is legitimate given the risks versus benefits.
 - Examine current ETT depth, size, patency, location.
 - Evaluate sedative-analgesic needs, cardiopulmonary response to procedure.
 - Assemble nursing, respiratory therapy, physician assistance as needed.
 - Assure immediate access to difficult airway cart, code cart, resuscitative drugs.
 - An imperative action by the airway team is a preexchange airway assessment. Performed externally and internally, this assessment will allow risk stratification, assessment of airway status, and planning of the exchange procedure. Pre-exchange laryngoscopy affords airway assessment as a segue to improved airway care. Assessment, best performed with VAL, may uncover partial/total ETT extubation masquerading as a “cuff leak” or offer a vital glimpse when there is overwhelming airway edema and secretions that render a high-risk warning for the exchange. In the case of elective ETT exchange—i.e., change of size or location—an alternative may be to delay or abort the exchange or choose to perform a surgical airway. Urgent or emergent exchanges—i.e., cuff perforation, narrowed lumen—may proceed but with a clear understanding of the airway status to optimize procedural planning.
- VAL placement followed by removal and ETT replacement
- Combined VAL+AEC
- Combined VAL+FFB±AEC
- ETT exchange options (nasal to oral, oral to nasal)
 - Similar to above exchange options
 - Safest method for a location change would offer continuous airway access, thus, for example, VAL assessment followed by passing an AEC via the nasally placed ETT, backing out existing ETT above the glottis via the AEC, optimize VAL view, and then freehand ETT advancement. Once the ETT is in position, the AEC may be removed. Conversely, an ETT may be delivered via FFB or DL if visualization is adequate.
 - Maintaining continuous access affords “backtracking” if advancement of the new ETT is disrupted. Either the existing ETT or a new ETT may be readvanced into the airway over the indwelling AEC.
 - Fundamentals of airway management must be practiced, even when use of high-tech equipment is incorporated.
 - Proper positioning is an absolute (e.g., ramping the obese patient).
 - Secretions, vomitus, bleeding impede viewing. Apply suction to optimize view.
 - Assemble equipment and staff and discuss primary and back-up plans.
 - 100% oxygen, suction ETT if applicable
 - Provide appropriate sedatives and analgesics and consider the pro/cons of neuromuscular blocking agents.
 - Prior to the exchange, assign tasks to team members to assure each is aware and comfortable with his or her role in the exchange.
 - Apply liberal lubrication to the blade and ETT to ease passage.
 - Double glove for procedure. If gloves become slippery from lubrication, assistant can remove outer glove(s).
 - “Mind the gap” between the ETT and the airway exchange catheter. An attempt to minimize the gap is imperative. The ETT will pass with less “wobble” and reduce hangup on airway tissues. In some instances, a smaller AEC is the only option (double-lumen tube, existing small-caliber ETT, luminal narrowing or kink). The replacement ETT—e.g., 8-mm ETT—must be advanced over a smaller AEC with an increased risk of ETT hangup, multiple attempts, delay in oxygenation, and other airway and hemodynamic complications. The smaller AEC may “bow” laterally in the airway when force is applied to the advancing ETT. The ETT may veer laterally and impinge on airway tissues, particularly the epiglottis, arytenoid, and vocal cords. Resistance may ensue. This major point promotes two important concepts; minimize the gap and deploy VAL to optimize viewing capabilities.
 - If clinical conditions dictate that a smaller diameter AEC be utilized, the Cook brand Aintree catheter can be used as a “jacket” for the 11F and 14F Cook AEC. Its placement on the AEC will reduce wobble, narrow the gap, and increase the “rigidity” of the AEC.
 - Beware of the depth markings on the AEC and coordinate them with those markings on the ETT. It is imperative that personnel be assigned to stabilize the AEC during removal and replacement of the ETTs. Awareness of the AEC depth is important to minimize distal or proximal migration; both could have devastating consequences.
 - The exchange method with the highest first-pass success rate, fewest attempts, lowest incidence of desaturation, and overall success is combining VAL+AEC, particularly in the known or suspected difficult airway patient.
 - Further, unpublished data from the Hartford Hospital Exchange database strongly suggests that incorporating the larger diameter AEC will markedly improve first-pass success and reduce desaturation and other airway-related complications.

Contraindications

- Inadequate equipment, personnel in high-risk patients
- Delay or abort exchange or alternatively, perform a surgical airway

Equipment

Equipment needs include all contents of the difficult airway cart, capable suction apparatus, and airway exchange catheters (AEC, various diameters) (Figs. E1-43 through E1-50).

ANATOMY

Periglottic airway anatomy has been reviewed in previous sections. The primary concerns for an ETT exchange are access to the oral cavity via the nose or mouth and the patency of the airway in regard to adequate room to place the new ETT across the supraglottic, glottic, and subglottic regions. VAL offers a clear advantage over conventional DL or FFB methods.

PROCEDURE

- Multiple choices exist for ETT exchange. Currently, the safest method would be to maintain continuous access to the airway via an indwelling AEC or placement of both the existing and new ETT across the glottic opening. The latter is occasionally possible when, for example, the existing ETT is small—e.g., 6.0—in a tall male patient (relatively large glottic opening).
- Options for ETT exchange (oral to oral)
 - Blinded ETT removal followed by DL, VAL replacement (maybe required with ETT obstruction or damage)
 - DL placement, ETT removal, and freehand replacement
 - FFB assisted (either passing FFB through glottis with or without existing ETT present)
 - AEC assisted (without the benefit of laryngoscopy to open the airway to provide a pathway for advancement)
 - Combined DL+AEC

AFTER PROCEDURE

Postprocedure Care

- Following advancement of ETT into the trachea and reverifying its position, stabilize the ETT in position, and remove the AEC.
- Standard methods of determining the ETT position, such as capnography and chest auscultation, are recommended. FFB may also be helpful.

Complications

- Passing an AEC into an ETT without knowledge of its relative location—e.g., intratracheal versus supraglottic position in unrecognized extubation masquerading as a “cuff leak”—could lead to esophageal intubation, interruption of oxygen delivery, or loss of the airway. Hence, a preexchange laryngoscopy, preferably VAL based, is recommended.
- Airway related
 - Desaturation, esophageal intubation, regurgitation, aspiration
 - Main stem bronchus intubation, mucosa injury, tracheobronchial wall injury, pneumothorax
 - Loss of airway, need for accessory devices
 - Lip, dental, tongue, pharyngeal injury
 - Tracheobronchial and/or ETT obstruction from distal soilage/secretions
- Hemodynamic related
 - Tachycardia, bradycardia
 - Hypertension, hypotension
 - Dysrhythmia, cardiac arrest

OUTCOMES AND EVIDENCE

- Despite the serious clinical implications of ETT exchange, there is a relative paucity of evidence-based literature regarding best practice for ETT exchange. Maintaining continuous access to the airway is, however, a consistent recommendation. Many serious and potentially life-threatening complications can accompany exchange procedures. Recent evidence suggests patients with a known/suspected difficult airway or poor visualization offered by DL during the preexchange airway assessment may benefit greatly by incorporating VAL+AEC.
- The value of a preexchange airway assessment (VAL) is demonstrated in its ability to diagnose otherwise unrecognized partial/complete tracheal extubation masquerading as a cuff leak.

- Exchanging a double-lumen tube (DLT) to a single-lumen tube (or vice versa) typically is more difficult due to (1) the larger diameter, angled DLT possibly being difficult to place in general, and (2) AEC-assisted exchange often entailing the use of a smaller caliber AEC because the DLT's smaller luminal diameter will not accept the larger AEC.
- The overall usefulness of video-based visualization of the “easy” airway is questionable except for evaluation and educational purposes. However, its use for the restricted laryngeal view with DL, for the difficult airway (either known or presumed), and for its role as a rescue device for failed DL is without question a welcome addition to our airway arsenal.
- VAL serves a variety of roles in airway management in the ICU setting, well beyond simply tracheal intubation. Extubation evaluation, ETT exchange, rescue of DL failures, plus its use as a primary management choice are but a few.

Advances in ultrasound technology continue to enhance its diagnostic applications in daily medical practice. Constantly evolving, this tool has become useful to properly trained cardiologists, anesthesiologists, intensivists, surgeons, obstetricians, and emergency department physicians. Ultrasound can enable rapid, accurate, and noninvasive diagnosis of a broad range of medical conditions. Patients in the intensive care unit (ICU) present daily diagnostic and therapeutic challenges to the medical team. The availability of ultrasound instrumentation in critical care units has facilitated greatly the evaluation and treatment of patients with a wide spectrum of conditions. Although transesophageal echocardiography (TEE) previously was the principal diagnostic approach using ultrasound to evaluate ICU patients, advances in ultrasound imaging, including harmonic imaging, digital acquisition, and contrast for endocardial enhancement, have improved the diagnostic yield of TTE, which is simpler and safer to perform. Ultrasound devices continue to become even more portable than in the past, and hand-carried devices now are readily available for bedside applications. This chapter discusses the application of bedside ultrasonography in the ICU. The emphasis is on echocardiography and cardiovascular diagnostics. The use of bedside ultrasound to facilitate central line placement and to aid in the care of patients with pleural effusions and intraabdominal fluid collections also is addressed.

USE OF BEDSIDE ULTRASONOGRAPHY IN THE INTENSIVE CARE UNIT

General Indications

Ultrasonography has become an invaluable tool in the management of critically ill patients. Its safety and portability allow for use at the bedside to provide rapid, detailed information regarding the cardiovascular system¹ and the function and anatomy of certain internal organs. It also can be used by the clinician to assess the pleural and intraabdominal spaces and to perform some invasive procedures safely. General indications for performance of echocardiography in the ICU are listed in [Box E2-1](#). [Box E2-2](#) lists major indications for performance of primary TEE in the ICU. Other indications for use of bedside ultrasonography by the intensivist in critically ill patients are listed in [Box E2-3](#).

Technical Aspects

Acoustic Window in a Critically Ill Patient

The practical value of bedside ultrasonography in the management of critically ill patients is now widely accepted despite the inherent limitations of the technique.² These limitations are related mostly to suboptimal imaging conditions that commonly are encountered when performing studies of critically ill patients. The constrained physical environment of the ICU also can compromise the quality of the images obtained. For an ultrasound study to be deemed adequate, a good acoustic “window” is required to allow accurate analysis. Ultrasonography uses the physical principle that sound is reflected from tissue interfaces, allowing a two-dimensional (2D) image of the anatomic structure studied to be constructed.³ Anything hindering the reflection of this acoustic signal—air, bone, calcium, a foreign body, or another interposed structure—interferes with ultrasound transmission and diminishes the overall quality of the examination. In the ICU, many patients are mechanically ventilated. In these patients, adequate

imaging can be limited by pneumothorax, pneumomediastinum, or subcutaneous emphysema.² Other important factors limiting data acquisition in critically ill patients are related to surgical wounds and dressings, tapes, tubing, obesity, and chronic obstructive pulmonary disease. In addition, lack of patient cooperation and the impossibility of moving some patients into the optimal position for the examination contribute to a high prevalence of technically inadequate studies.²

Although ultrasonography permits evaluation of the structure and function of the heart and other important organs and structures, acquisition of data and interpretation of results are fraught with potential traps.⁴ Performing an ultrasound examination requires a thorough knowledge of anatomy and instrumentation, including attention to gain control, grayscale settings, Doppler velocity settings, and transducer placement.

Preparation of the Patient

Before starting an ultrasound examination at the bedside in the ICU, certain important criteria should be fulfilled. The criteria vary depending on the type of examination being performed (transthoracic echocardiography [TTE]; TEE; vascular, abdominal, or thoracic ultrasound) and on certain patient-related factors (e.g., presence or absence of mechanical ventilation, nasogastric tube, or surgical dressings).

An awake patient should be informed about the importance of the ultrasound investigation and should be provided with an explanation of how the clinician will perform the examination.³ These steps are especially important when the examination uses the transesophageal route.

Positioning

Proper positioning of the patient is important for obtaining an adequate image. For performance of TTE and TEE in patients who are not mechanically ventilated, optimal imaging usually is obtained by having the patient in the left lateral decubitus position. Taking the extra 5 minutes to position the patient on his or her left side for TTE often results in much improved image quality and minimizes aspiration risk for TEE. Adequate positioning of the patient varies depending on the structures being assessed for other ultrasound imaging (e.g., pleural space, peritoneal cavity, vascular structures, or bladder). Care must be taken when positioning a critically ill patient in bed, because these patients often have multiple vascular catheters, an endotracheal tube, drains, and other tubes or devices connected to them. When the ultrasound examination is done to localize and mark pleural or abdominal fluid collections for subsequent drainage, it is crucial that the patient remain in the same position used during the marking procedure until the actual drainage of the collection is performed. Risks of perforating surrounding organs (e.g., heart, spleen, liver, lungs, or bowel) and inducing significant morbidity are increased if the drainage is performed in a position different from the one used during marking.

Sedation

To optimize the ultrasound examination, the patient must be cooperative and nonagitated. Noninvasive procedures such as TTE and abdominal ultrasound usually are well tolerated by patients, and additional sedation rarely is needed to perform these procedures. When performing TEE, however, certain precautions need to be taken. Patients should fast (or have their tube feeds stopped) for at least 4

BOX E2-1**General Indications for Performance of an Echocardiographic Examination in the Intensive Care Unit**

Hemodynamic instability
 Ventricular failure
 Hypovolemia
 Pulmonary embolism
 Acute valvular dysfunction
 Cardiac tamponade
 Complications after cardiothoracic surgery
 Infective endocarditis
 Aortic dissection and rupture
 Unexplained hypoxemia
 Source of embolus

BOX E2-2**Major Indications for Performance of Primary Transesophageal Echocardiography Study in the Intensive Care Unit**

Diagnosis of conditions in which the superior image quality is vital (e.g., aortic dissection, assessment of endocarditis and its complications, intracardiac thrombus)
 Imaging of structures that may be inadequately seen by TTE (e.g., thoracic aorta, left atrial appendage, prosthetic valves)
 Echocardiographic examinations of patients with conditions that prevent image clarity with TTE (e.g., severe obesity, emphysema, mechanical ventilation with high level of PEEP, presence of tubes, surgical incisions, dressings)
 Acute perioperative hemodynamic derangements

PEEP, positive end-expiratory pressure; TTE, transthoracic echocardiography.

BOX E2-3**Other Indications for Use of Bedside Ultrasonography by the Intensivist**

Central line placement
 Assessment of pleural effusions and intraabdominal fluid collections
 Urinary bladder scan
 FAST
 Intraaortic balloon counterpulsation
 Ventricular assist devices

FAST, focused assessment of the trauma patient.

hours before the procedure. Topical anesthesia of the oropharynx also is helpful before insertion of the TEE probe, especially in patients who are not endotracheally intubated.³ Even if adequate topical anesthesia is provided, insertion of the TEE probe still can cause significant discomfort and anxiety, so providing adequate sedation and analgesia is important. Frequently used sedative or analgesic agents include intravenous (IV) midazolam, fentanyl, and propofol. Dosing should be titrated according to clinical parameters including arterial blood pressure, minute ventilation, and arterial oxygen saturation.³ Sedative-induced hypotension is a frequent problem in patients with depressed ventricular function or decreased systemic vascular resistance, and occasionally patients may require transient support with IV volume infusion or rarely a vasopressor agent. If the patient is extremely uncooperative and biting, transient paralysis accompanied by increased sedation may have to be used to perform TEE safely.

Monitoring During the Procedure

Most ICU patients are monitored continuously, at least for certain respiratory, cardiac, or hemodynamic parameters. It is essential that

BOX E2-4**Contraindications to Insertion of Transesophageal Echocardiography Probe****Absolute Contraindications**

Esophageal pathologies
 Stricture
 Mass or tumor
 Diverticulum
 Mallory-Weiss tear
 Dysphagia or odynophagia not previously evaluated
 Cervical spine instability

Relative Contraindications

Esophageal varices
 Recent esophageal or gastric surgery
 Oropharyngeal carcinoma
 Upper gastrointestinal bleeding
 Severe cervical arthritis
 Atlantoaxial disease

patients undergoing an ultrasound examination in the ICU be monitored at least with noninvasive recording of blood pressure, pulse oximetry, and electrocardiogram. Even TTE or abdominal ultrasound examinations can be associated with inadvertent pulling of tubes or drains, and anxiety can be encountered during the procedure. Because of its more invasive nature, TEE may induce complications such as increased agitation, respiratory distress, and discomfort during insertion of the probe. These effects can be associated with substantial changes in blood pressure and ventilatory status. Administration of sedatives and sometimes paralytic agents can induce further changes in hemodynamic and respiratory status.^{3,5}

Safety

Performance of ultrasound examinations in the ICU allows procedures that previously required transport to the radiology suite to be performed at the bedside. This is an important advantage to a critically ill patient, because transport out of and back to the ICU is known to be associated with increased risk of complications.⁶ Performance of bedside TTE and of other noninvasive ultrasound examinations is safe and not associated with significant risks to the patient. Performance of bedside TEE also is associated with a low incidence of serious complications (<0.5% in the general population and the elderly).⁵ The reported mortality rate associated with TEE is 0.01% to 0.03%.⁷ Most patients undergoing TEE examinations in the ICU usually are receiving mechanical ventilation and have continuous monitoring of arterial blood pressure, electrocardiogram, and oxygen saturation.⁸ Transient hypotension, typically attributable to administration of sedative medications, usually can be treated with vasopressors or IV fluids or both. The risk of injury to the pharynx or esophagus is greater in anesthetized and endotracheally intubated critically ill patients than in awake patients, because anesthetized patients cannot assist with probe insertion by swallowing and do not resist when insertion is difficult.⁸ Increased difficulty in directing the TEE probe also can be encountered owing to the presence of a nasogastric tube. Coagulopathy and thrombocytopenia, common problems in critically ill patients, can increase the risk of hemorrhage due to mucosal injury during blind insertion of the TEE probe. Daniel et al.⁹ reported significant complications related to TEE in 18 (0.18%) of 10,218 examinations. In 11 studies reporting on 943 patients undergoing TEE, the rate of complications was 1.7%.⁵ Serious complications occurred in only two patients (0.2%). Colreavy et al.⁸ studied the safety and utility of TEE performed by ICU physicians in 255 critically ill patients and showed that TEE was associated with a complication rate of only 1.6%. It is reasonable to conclude that TEE is associated with few complications, given the high severity of illness among ICU patients.⁵ Close monitoring of hemodynamic and oxygenation parameters is essential. **Box E2-4** lists specific contraindications to the insertion of a TEE probe.

BEDSIDE ECHOCARDIOGRAPHY IN A CRITICALLY ILL PATIENT

Echocardiography can provide diagnostic information noninvasively regarding cardiac structure and mechanical function. The supplementary information provided by this technique can help determine the cause of hypotension refractory to inotropic support or vasopressor infusions.³ It also can help in the diagnosis of a wide spectrum of other cardiovascular abnormalities and guide therapeutic management. An adequate understanding of the proper use of echocardiography is a prerequisite for the intensivist. General indications for performance of an echocardiographic examination in the ICU are listed in [Box E2-1](#).

Transthoracic Versus Transesophageal Echocardiography in a Critically Ill Patient

Accurate and prompt diagnosis is crucial in the ICU. The easiest and least invasive way to image cardiac structures is TTE.³ This noninvasive imaging modality is of great value in the critical care setting because of its portability, widespread availability, and rapid diagnostic capability. In the ICU, TTE in certain cases may fail to provide adequate image quality because of different factors that potentially can hinder the quality of the ultrasound signal, as was described previously. The failure rate (partial or complete) of TTE in the ICU has been reported to be 30% to 40%.^{10,11} Improvements have been made in transthoracic imaging (e.g., harmonics and contrast and digital technologies), however, resulting in a lower failure rate of TTE in the ICU (10%-15% in our institution).

TEE is particularly useful for evaluation of suspected aortic dissection, prosthetic heart valves (especially in the mitral position), source of cardiac emboli, valvular vegetations, possible intracardiac shunts, and unexplained hypotension. TEE allows better visualization of the heart in general and especially the posterior structures, owing to the proximity of the probe and favorable acoustic transmission.¹ TTE also has limitations, however. For several areas of the heart and great vessels, TEE may provide limited images. The view of the left ventricular apex often is foreshortened with TEE, and an apical left ventricular clot can be missed. TTE usually is superior for visualization of the apex. Because of interposition of the left mainstem bronchus, the superior portion of the ascending aorta is another important area that may not be well visualized with TEE. With TEE, transducer position and angulation are constrained by the relative positions of the esophagus and heart. The relatively fixed relationship between the position of the probe and the heart often makes it impossible to align the Doppler beam parallel to the flow of interest (e.g., to evaluate the jet of blood resulting from aortic stenosis). In addition, the 2D image planes of TEE often make standard anatomic measurements more difficult to obtain.

As a result of the significantly improved technical quality of TTE, most ICU patients can be studied satisfactorily with this modality. Immediate TEE is still preferable, however, in certain specific clinical situations in which TTE is likely to fail or be suboptimal.¹¹ The major indications for primary TEE in the ICU^{12,13} are listed in [Box E2-2](#). Even when TEE is necessary, data from the TTE examination are often essential for the final clinical interpretation.

Hemodynamic Evaluation Ventricular Function

Left Ventricular Systolic Function. Evaluation of left ventricular performance by echocardiography is often paramount in the ICU. Accurate and timely assessment of systolic function should be an integral part of the medical management of hemodynamically unstable critically ill patients. Global assessment of left ventricular contractility includes the determination of ejection fraction (EF), circumferential fiber shortening, and cardiac output.

The simplest quantitative approach is to measure the mid-left ventricular short-axis dimension at end diastole and end systole for deter-

mination of the percent fractional shortening. Fractional shortening is related directly to EF; normal fractional shortening is 30% to 42%.¹

$$\text{Fractional shortening} = \frac{\text{End-diastolic dimension} - \text{End-systolic dimension}}{\text{End-diastolic dimension}}$$

In the setting of regional wall motion abnormalities, fractional shortening may underestimate or overestimate global ventricular function and must be interpreted in light of what is seen in all of the 2D imaging planes of the ventricle.¹⁴

Global systolic ventricular function also can be assessed quantitatively by fractional area change (normal value is 36% to 64%)¹⁵ and EF (normal value is 55% to 75%) ([Fig. E2-1](#)):

$$\text{Fractional area change} = \frac{\text{End-diastolic area} - \text{End-systolic area}}{\text{End-diastolic area}}$$

$$\text{Ejection fraction} = \frac{\text{End-diastolic volume} - \text{End-systolic volume}}{\text{End-diastolic volume}}$$

These measurements require good image quality, because endocardial border contours must be traced (see [Fig. E2-1](#)). Machine-integrated software computes the data and provides volumes, areas, and the resultant EF (see [Fig. E2-1](#)). In patients with regional wall motion abnormalities, more precise measures of stroke volume can be made by approximating ventricular volumes as a stack of elliptical disks on biplane imaging (modified Simpson's method).^{1,15}

In the critical care setting, endocardial border definition may be suboptimal because of poor image quality.^{10,16,17} In these cases, global ventricular function often is assessed qualitatively by visual inspection alone. This method has been found to be reliable when used by experienced clinicians.¹⁸ By simple visualization of the kinetics and size of the cardiac cavities in real time, an experienced intensivist with a sufficient echocardiographic background can establish a functional diagnosis immediately.

Analysis of regional wall motion includes a numeric scoring system to describe the movement of the different regions of the left and right ventricle (1 = normokinesia; 2 = hypokinesia; 3 = akinesia; 4 = dyskinesia; 5 = aneurysmal change).¹⁵ Visualized from the short-axis view of the left ventricle, a complete overview of myocardial areas perfused by the three major coronary arteries can be obtained ([Fig. E2-2](#)). If the TTE examination is technically difficult and the endocardium is poorly visualized, harmonic imaging and possibly contrast, if needed, can dramatically improve endocardial border visualization and subsequent evaluation of global systolic function (as discussed further later in this chapter). For the remaining few technically challenging cases with suboptimal TTE, performance of TEE allows for a more precise evaluation of ventricular function in most critically ill patients because of the higher image quality that can be obtained with this echographic modality.

Left Ventricular Failure in the Intensive Care Unit. In a critically ill patient with unexplained hemodynamic instability, determination of cardiac function is an integral part of the medical management. Echocardiography is valuable in this setting because the clinical examination and invasive hemodynamic monitoring often fail to provide an adequate assessment of ventricular function. In a study by Fontes et al.¹⁹ that compared pulmonary artery (Swan-Ganz) catheterization and TEE, the overall predictive probability for conventional clinical and hemodynamic assessment of normal ventricular function was 98%, whereas for abnormal ventricular function (EF <40%), it was 0%. Several other studies have reported similar results.²⁰⁻²² Assessment of biventricular function is one of the most important indications for performance of echocardiography in the ICU. In a study by Bruch et al.,²³ 115 critically ill patients were studied by TEE. The most common indication for TEE was hemodynamic instability (67% of patients). Of these hemodynamically unstable patients, 20 (26%) were found to have significant left ventricular dysfunction (EF <30%). In a study by McLean²⁴ of the use of TEE in the ICU, the most common

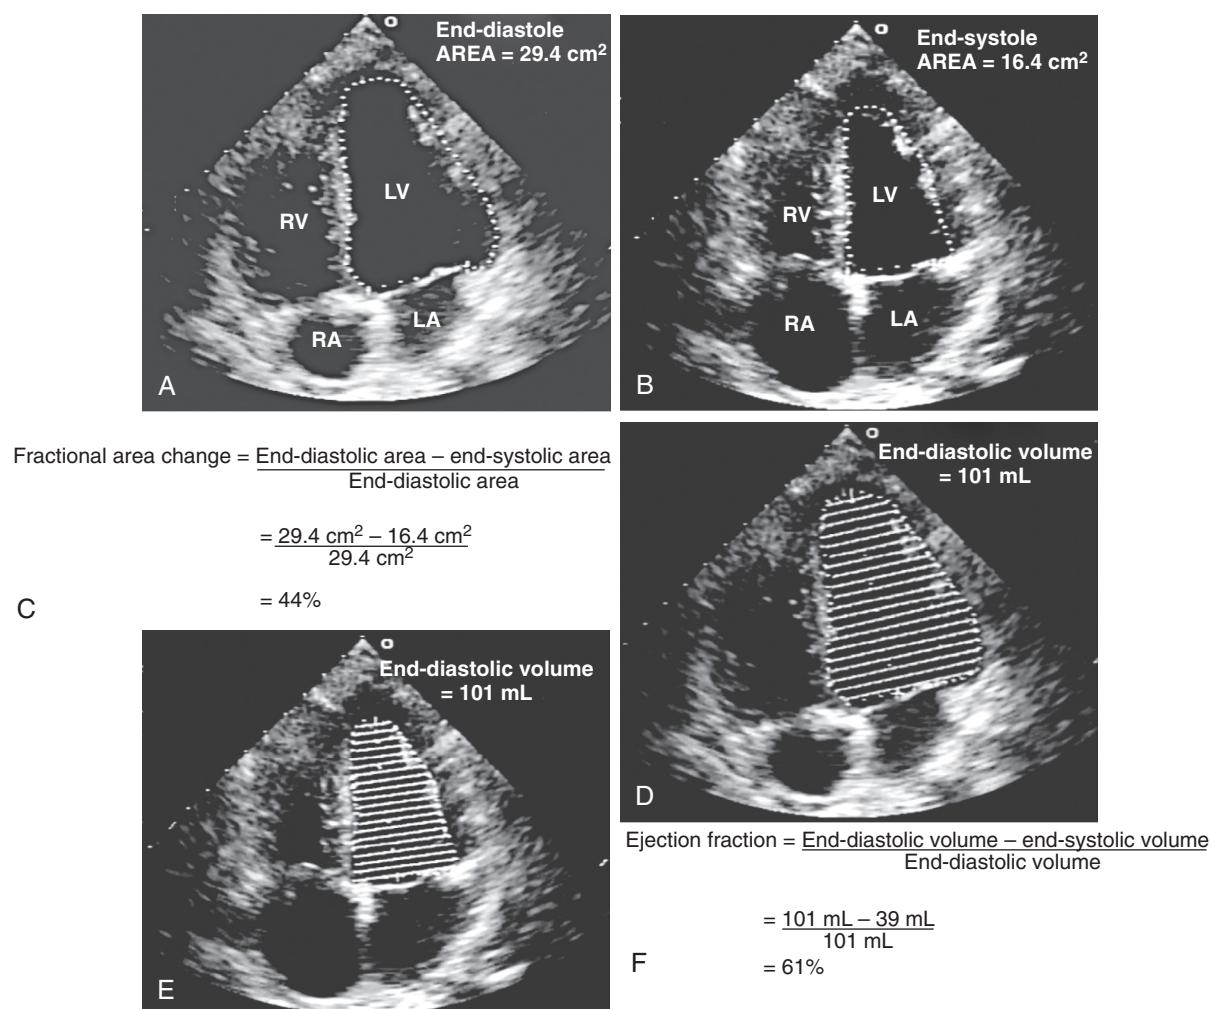

FIGURE E2-1 ■ Fractional area change and ejection fraction calculation. Endocardial contour of the left ventricular cavity is traced at end diastole (A) and at end systole (B) in the transthoracic apical four-chamber view. Machine-integrated software computes the data and gives corresponding end-diastolic and end-systolic areas. Fractional area change can be calculated with these data (C). Normal values are 36% to 64%.¹⁵ Corresponding end-diastolic (D) and end-systolic (E) volumes are computed using the modified Simpson's method. The data are used to calculate the ejection fraction (F). Normal values are 55% to 75%. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

reason to request a TEE was assessment of left ventricular function. In most patients, left ventricular function was assessed adequately by TTE before TEE. In a study by Vignon et al.,¹⁷ TTE allowed adequate evaluation of global left ventricular function in 77% of mechanically ventilated ICU patients. Although TEE was needed for most other indications, TTE was shown to be an excellent diagnostic tool for assessment of left ventricular function in the ICU (Fig. E2-3) even when positive end-expiratory pressure is present.

Several important points should be emphasized: (1) Significant left ventricular dysfunction is common in critically ill patients; (2) ventricular function should be assessed in all patients with unexplained hemodynamic instability, because this information is particularly important for guiding resuscitation and informing decisions regarding subsequent medical or surgical management; (3) it is now possible to obtain adequate information about ventricular function in most ICU patients using TTE, but TEE provides better accuracy in patients with suboptimal imaging by TTE.

Sepsis-Related Cardiomyopathy. Classically, septic shock has been considered a “hyperdynamic” state characterized by normal or high cardiac output. Echocardiographic studies indicate that ventricu-

lar performance often is markedly impaired in patients with sepsis.²⁵⁻²⁷ Parker et al.²⁸ were the first to describe left ventricular hypokinesis in septic shock. They reported that survivors manifested severely depressed left ventricular EF but that adequate left ventricular stroke output was maintained as a result of acute left ventricular dilation.²⁹ Jardin et al.²⁵ studied 90 patients with septic shock and performed daily bedside assessments of left ventricular volume and left ventricular EF using TTE. They observed that left ventricular EF was significantly depressed in all patients, resulting in severe reductions in left ventricular stroke volume. Of these patients, 34 (38%) eventually were weaned from hemodynamic support and showed gradual improvement in left ventricular EF and ultimately recovered. The remaining 56 patients (62%) eventually died (of early circulatory failure or late multiple organ failure). In this subset, the degree of left ventricular dysfunction was less than in survivors but failed to improve over time. The severity of left ventricular dysfunction does not predict outcome. A paradoxical relationship between the degree of left ventricular dysfunction and the likelihood of recovery also has been described by others.^{25,28,30,31} Among patients who survive, left ventricular dilation and systolic dysfunction usually are reversible.

Left ventricular EF might not be a reliable index of left ventricular systolic function in patients with early septic shock because this is a state characterized by low systemic vascular resistance that unloads the left ventricle.²⁵ Normal or supranormal EF in early sepsis might lead clinicians to make the wrong inference about cardiac reserve because left ventricular EF might decrease if afterload is increased by the administration of vasopressor agents.

Left Ventricular Diastolic Function. In the ICU, diastolic dysfunction should be suspected when ventricular filling pressure (pulmonary capillary wedge pressure) is elevated and EF is normal or supranormal.¹ The diastolic properties of the ventricle often are assessed by evaluating Doppler echocardiographic mitral inflow and pulmonary venous flow patterns. Mitral inflow, as measured by pulsed wave Doppler at the tips of the mitral leaflets, is characterized by an early filling phase (E wave) followed by atrial systole, resulting in

FIGURE E2-2 ■ Transthoracic short-axis echocardiographic view of the left (LV) and right (RV) ventricles at the midpapillary muscle level. In this tomographic view of the heart, areas of myocardium and papillary muscles (AL, anterolateral; PM, posteromedial) supplied by all three major coronary arteries are represented. ANT, anterior; AS, anteroseptal; INF, inferior; IS, inferoseptal; LAT, lateral.

additional filling (A wave) (Fig. E2-4). The transmitral Doppler pattern always should be interpreted in conjunction with pulsed wave Doppler of the pulmonary venous flow, which is characterized by a systolic phase (S), a diastolic phase (D), and an atrial phase (AR) from reversal of flow into the pulmonary veins during atrial contraction (Fig. E2-5). These filling patterns are related to the intrinsic diastolic properties of the myocardium and are influenced by many different factors, particularly left atrial pressure, heart rate, ischemia, ventricular hypertrophy, and valvular pathologies. Only modest correlation has been found between Doppler indices of diastolic function and parameters measured using more invasive means.^{32,33} Integrated interpretation of mitral and pulmonary venous flow patterns may be useful for diagnosing abnormal myocardial relaxation (e.g., owing to hypertensive heart disease, hypertrophic cardiomyopathy, or coronary ischemia) or restrictive pathology (e.g., owing to cardiomyopathy, constrictive pericarditis, coronary artery disease, cardiac transplantation, or dilated cardiomyopathy). Nevertheless, these findings must be interpreted with caution when caring for critically ill patients, given the many different factors that can acutely influence flow patterns in this population of patients.

Right Ventricular Function and Ventricular Interaction. Abnormal right ventricular function often plays an important and sometimes underestimated role in the pathogenesis of critical illness.³⁴⁻³⁶ Based on an echocardiographic definition,³⁷ massive pulmonary embolism and

FIGURE E2-4 ■ Normal mitral inflow profile as measured by transthoracic pulsed wave Doppler at the tips of the mitral leaflets. It is characterized by an early filling phase (E wave) followed by atrial systole (A wave), which results in additional filling. These filling parameters are related to intrinsic diastolic myocardial properties and can be influenced by many different factors (see text).

FIGURE E2-3 ■ **Dilated cardiomyopathy.** Transthoracic examination of a severely dilated left ventricle (LV) in the parasternal long-axis (A) and apical four-chamber (B) views. The 65-year-old patient presented with flash pulmonary edema and later was found to have severe diffuse coronary artery disease. LA, left atrium; RA, right atrium; RV, right ventricle.

FIGURE E2-5 ■ Normal pulmonary venous flow profile as measured by transthoracic pulsed wave Doppler with the sample volume placed in the right superior pulmonary vein. It is characterized by a predominant systolic wave (S), a diastolic wave (D), and an atrial wave (AR) (from reversal of flow into the pulmonary veins occurring during atrial contraction). The pulmonary venous flow profile always should be interpreted in conjunction with the transmitral Doppler pattern to have a more complete assessment of diastolic function.

acute respiratory distress syndrome are the two main causes of acute cor pulmonale in adults.³⁸ In the critical care setting, right ventricular function also can be altered by any other perturbations that increase right ventricular afterload, such as positive end-expiratory pressure or increased pulmonary vascular resistance (from vascular, cardiac, metabolic, or pulmonary causes). Depressed right ventricular systolic function is also often associated with right ventricular infarction, most commonly in the setting of inferior myocardial infarction. Acute sickle-cell crisis, air or fat embolism, myocardial contusion, and sepsis are other causes of acute right ventricular dysfunction.

Adequate assessment of right ventricular function is important when caring for hemodynamically unstable, critically ill patients, specifically patients with massive pulmonary embolism and acute respiratory distress syndrome, because the diagnosis of concomitant significant right ventricular dysfunction may alter therapy (e.g., fluid loading, use of vasopressors, use of thrombolytics) and provide information about prognosis.^{38,39} Echocardiographic examination of the right ventricle requires primarily an assessment of the size and kinetics of the cavity and septum.^{37,40} Normally the right ventricle appears relatively flat. As it dilates, the apical region of the right ventricle becomes more rounded (Fig. E2-6). In the short-axis view, the right ventricle, which usually has a crescentic shape, becomes oval because of septal displacement and bulging of the right ventricular free wall (see Fig. E2-6).¹ Right ventricular size and function generally are evaluated by visual comparison with the left ventricle. Right ventricular diastolic dimensions can be obtained by measuring right ventricular end-diastolic area in the long axis, from an apical four-chamber view, using either TTE or TEE.

Because pericardial constraint necessarily results in left ventricular restriction when the right ventricle acutely dilates (i.e., there is ventricular interaction), one of the best ways to quantify right ventricular dilation is to measure the ratio between the right ventricular and left ventricular end-diastolic areas, an approach that cancels out individual variations in cardiac size.^{37,40} Moderate right ventricular dilation corresponds to a diastolic ventricular ratio greater than 0.6; severe right ventricular dilation corresponds to a ratio greater than or equal to 1.^{37,40} Right ventricular diastolic enlargement usually is associated with right atrial dilation, inferior vena caval dilation, and tricuspid regurgitation. When pressure in the right atrium exceeds pressure in the left atrium, the foramen ovale may open. Pressure and volume overload of the right ventricle can lead to distortion of left ventricular geometry and abnormal motion of the interventricular septum. With conditions of high strain imposed on the right ventricle (volume or pressure overload or both), the interventricular septum flattens, and the left ventricle appears to have a “D” shape (see Fig. E2-6).^{4,37} This “paradoxic” septal motion also is seen at the interatrial level.

Because the two ventricles are enclosed within the relatively stiff pericardium, the sum of the diastolic ventricular dimensions has to remain constant.⁴¹ Acute right ventricular or left ventricular dilation can occur only if it is associated with an acute and proportional reduction in left ventricular or right ventricular diastolic dimension (i.e., ventricular interaction). With acute right ventricular dilation, septal displacement impairs left ventricular relaxation; the opposite occurs with acute left ventricular dilation. In these situations, the pressure-volume relationships of the left and right heart chambers are altered, and information obtained from a pulmonary artery catheter could be misleading (e.g., high filling pressures are recorded despite normal or even low circulating volume).

Pulmonary Embolism

Hemodynamic instability from acute cor pulmonale as a consequence of massive pulmonary embolism is a relatively common occurrence in critically ill patients. Until more recently, contrast pulmonary angiography generally was regarded as the gold standard for the diagnosis of pulmonary embolism. Angiography is an invasive procedure, however, and carries the risk of major complications in patients with circulatory failure.⁴² Contrast-enhanced helical computed tomography (CT) is an accurate and noninvasive test that has replaced angiography for the diagnosis of pulmonary embolism. Even CT requires transportation of patients to a location outside of the ICU, however, and transport alone is associated with significant risks. Echocardiography is well suited for diagnosis of pulmonary embolism because it can be done within minutes at the bedside. The diagnosis of acute cor pulmonale at the bedside with TTE has good positive predictive value for massive pulmonary embolism.^{43,44} This technique can detect acute right ventricular dilation and dysfunction resulting from a large pulmonary embolism. The finding of right ventricular dilation and dysfunction is not specific for pulmonary embolism, however, because these findings may be observed with a variety of other conditions associated with increased right ventricular strain. In a study by McConnell et al.,⁴⁵ patients with acute pulmonary embolism were found to have a distinct regional pattern of right ventricular dysfunction with akinesia of the mid-free wall but normal motion at the apex by TTE. These findings contrasted with findings obtained in patients with primary pulmonary hypertension who had abnormal wall motion in all regions. Regional right ventricular dysfunction had a sensitivity of 77% and a specificity of 94% for the diagnosis of acute pulmonary embolism; positive predictive value was 71%, and negative predictive value was 96%. The presence of regional right ventricular dysfunction that spares the apex should raise the level of clinical suspicion for the diagnosis of acute pulmonary embolism.

Central pulmonary emboli are present in half of patients with symptoms of pulmonary embolism and acute cor pulmonale on TTE.⁵ Emboli lodged in the proximal pulmonary arteries usually cannot be visualized using TTE.⁵ Because other clinical conditions can produce acute cor pulmonale in the ICU, better visualization of the pulmonary arteries is needed to achieve high accuracy for the diagnosis of pulmonary embolism. This goal can be achieved by using TEE. TEE has good sensitivity for detecting emboli lodged in the main and right pulmonary arteries but is limited for the detection of more distal or left pulmonary emboli.^{5,46,47} If an embolus is visualized, the diagnosis is made. If the study is negative when the index of suspicion for pulmonary embolism is high, however, TEE must be followed up by a more definitive test such as angiography or helical CT. Also, when there is high clinical suspicion for pulmonary embolism but no emboli are visualized using TEE, the potential for nonthrombotic causes of pulmonary embolism (e.g., air or fat emboli) must be kept in mind.

The demonstration of acute cor pulmonale with echocardiography has important prognostic and therapeutic implications.^{48,49} The presence of cor pulmonale with massive pulmonary embolism is associated with increased mortality, whereas the absence of right ventricular dysfunction is associated with a better prognosis.³⁹ There is no consensus on the precise indications for administration of thrombolytics in massive pulmonary embolism complicated by acute cor pulmonale.^{50,51}

FIGURE E2-6 ■ Severe right ventricular failure and dilation. **A**, Normal transthoracic parasternal short-axis view of the left (LV) and right (RV) ventricles at the midpapillary muscle level. **B**, Normal transthoracic apical four-chamber view of the left ventricle and right ventricle. These pictures of a normal heart depict the relationship between the left ventricle and right ventricle, with the left ventricle being normally larger than the right ventricle and the interventricular septum bulging slightly toward the right ventricle. **C**, Transthoracic parasternal short-axis view of the left ventricle and right ventricle in a patient with severe right ventricular failure and dilation. The right ventricular cavity is seen to be much larger than the left ventricular cavity. Because of the high volume and pressure in the right ventricle, the interventricular septum is bulging toward the left. This gives the left ventricle a characteristic “D” appearance. **D**, Transthoracic apical four-chamber view of the same patient shows the inverse relationship between the left ventricular and right ventricular sizes. The right ventricular dilation can occur only if associated with a proportional reduction in left ventricular diastolic dimension (“ventricular interaction”). This reduction in left ventricular diastolic dimension significantly impairs left ventricular relaxation and changes the pressure-volume relationship of the left heart chambers. LA, left atrium; RA, right atrium.

A safe and reasonable strategy for managing critically ill patients with suspected massive pulmonary embolism is as follows:

1. Initially perform bedside TTE, looking for the presence of regional right ventricular dysfunction as described earlier. If the TTE examination is suboptimal, TEE should be performed.
2. If echocardiography is inconclusive or negative and the clinical suspicion of a pulmonary embolism remains high, a definitive confirmatory radiologic test (preferably helical CT) should be performed.

Assessment of Cardiac Output

Measurement of cardiac output remains a cornerstone in the hemodynamic assessment of critically ill patients. Thermodilution is considered the gold standard approach for determining cardiac output in most ICUs. Measurement of cardiac output using thermodilution requires placement of a pulmonary artery catheter (or at least central venous and arterial catheters); although a useful technique, it is invasive and potentially inaccurate. Unreliable values are particularly

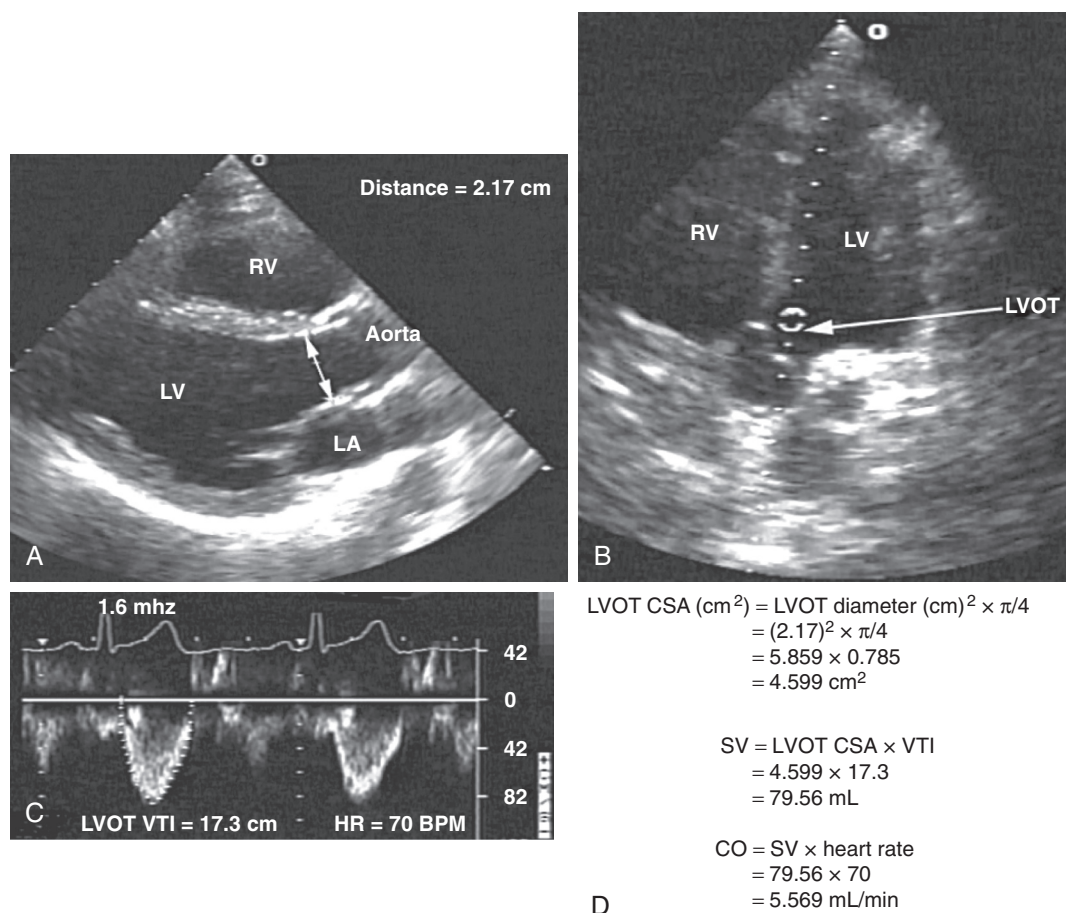

FIGURE E2-7 ■ Calculation of the stroke volume and cardiac output from the left ventricular outflow tract (LVOT). **A**, Left ventricular outflow tract diameter obtained from the transthoracic parasternal long-axis view, just below the insertion of the aortic valve leaflets. In this example, the left ventricular outflow tract diameter is 2.17 cm. **B**, Doppler interrogation (with pulsed wave Doppler) is performed from the apical view with the sample volume being placed in the left ventricular outflow tract, just below the aortic valve. **C**, Spectral Doppler tracing from the left ventricular outflow tract from which the transaortic flow velocity time integral (VTI) is derived. In this example, the VTI is 17.3 cm. **D**, The left ventricular stroke volume (SV) is obtained by measuring the cross-sectional area (CSA) of the left ventricular outflow tract (area [cm²] = left ventricular outflow tract diameter [cm]² × $\pi/4$) and multiplying by the transaortic VTI derived from the spectral Doppler tracing. The stroke volume is obtained by multiplying the heart rate to give the cardiac output (CO). LA, left atrium; LV, left ventricle; RV, right ventricle.

common in the presence of tricuspid regurgitation related to high pulmonary artery pressure. Several methods for determining cardiac output have been described using 2D and Doppler echocardiography. With this technique, stroke volume and cardiac output can be determined directly by combining Doppler-derived measurements of instantaneous blood flow velocity through a conduit with the cross-sectional area of the conduit. Blood flow can be calculated through various cardiac structures, including the pulmonary valve,⁵² mitral valve,^{53,54} and aortic valve.⁵⁵⁻⁵⁸ In the absence of intracardiac shunts, blood flow through these structures should be the same (continuity equation).⁵⁹ Of these methods, the one using the left ventricular outflow tract and aortic valve as the conduit is probably the most reliable and most commonly used. There is excellent agreement with thermodilution in most situations.⁵⁵⁻⁵⁸ The left ventricular stroke volume is obtained by measuring the cross-sectional area of the left ventricular outflow tract (area [cm²] = (left ventricular outflow tract diameter [cm]²) × ($\pi/4$), assuming that just below the aortic annulus, the left ventricular outflow tract is circular) multiplied by the transaortic flow

velocity time integral derived from a spectral Doppler tracing. The stroke volume obtained is multiplied by the heart rate to give the cardiac output: cardiac output = cross-sectional area × velocity time integral × heart rate (Fig. E2-7). With TTE, the left ventricular outflow tract diameter usually is obtained from the parasternal long-axis view, just below the insertion of the aortic valve leaflets. The Doppler interrogation is performed through the aortic valve from the apical view (see Fig. E2-7). With TEE, the left ventricular outflow tract diameter usually is obtained from the five-chamber view of the left ventricle. The transgastric view usually is used to obtain an apical long-axis view of the aortic valve through which Doppler interrogation is performed.⁶⁰ With either TTE or TEE, obtaining an accurate left ventricular outflow tract diameter and Doppler signal is essential to have an accurate cardiac output calculation. Because the measure of the left ventricular outflow tract diameter has a second-order relationship with the cross-sectional area (see previous formula), it is crucial that this measure be determined precisely. For the Doppler signal to be reliable, the Doppler sample must be parallel to the transaortic flow with an angle

of incidence not exceeding 20 degrees to avoid underestimation of transaortic velocity. Using TTE, McLean and coworkers⁶¹ showed an excellent correlation ($r = 0.94$) between cardiac output determined by the left ventricular outflow tract Doppler method and the thermodilution method in critically ill patients. Other studies have shown similar results.⁵⁵ In a study by Feinberg et al.,⁵⁸ cardiac output determined by TEE Doppler imaging was obtainable in 88% of 33 critically ill patients, and there was good correlation ($r = 0.91$) with the thermodilution method. Descorps-Declere et al.⁶⁰ also showed transgastric pulsed Doppler measurement across the left ventricular outflow tract with TEE to be a clinically acceptable method for cardiac output measurement in critically ill patients ($r = 0.975$ compared with the thermodilution method).

Another promising ultrasound-based technology to estimate cardiac output noninvasively in adults uses a small transesophageal Doppler probe to measure blood flow velocity waveforms in the descending aorta combined with a nomogram (based on height, weight, and age) for estimation of aortic cross-sectional area. This minimally invasive esophageal probe can be inserted easily in sedated patients and left in place safely for several days to provide continuous monitoring of cardiac function.^{62,63} Several technical problems can limit the accuracy of cardiac output measurements by esophageal Doppler monitoring,⁶² however, and although initial results are promising,⁶⁴⁻⁶⁶ more studies are needed to make a decision regarding the accuracy of this technique in critically ill patients.

Assessment of Filling Pressures and Volume Status

Adequate determination of preload and volume status is important for proper management of critically ill patients. Invasive pressure measurements to assess left ventricular filling are commonly used at the bedside to make inferences regarding left ventricular preload. These pressure measurements correlate only weakly with left ventricular volume, however.⁶⁷ Data from invasive monitoring using pulmonary artery catheterization may be misleading because ventricular compliance is altered secondary to numerous factors.^{68,69} Differences in diastolic compliance among patients may account for the weak correlation between pressure and volume and may limit the ability to use pressure measurements alone to derive information concerning left ventricular preload.¹⁴ Echocardiography can be helpful for adequately assessing preload. Parameters that can be measured using 2D imaging are left ventricular end-diastolic volume and left ventricular end-diastolic area. Using Doppler interrogation, additional information—mainly transmitral diastolic filling pattern and pulmonary venous flow—can be obtained.

Two-Dimensional Imaging. Echocardiography has been validated for left ventricular volume measurements.¹⁵ Subjective assessment of left ventricular volume by estimating the size of the left ventricular cavity in the short-axis and long-axis views is often adequate to guide fluid volume therapy at the extreme ends of cardiac filling and function. More precise quantitative values are desirable, however, and can be obtained by using endocardial border tracing (as described earlier). The normal left ventricular end-diastolic volume as determined by echocardiography is 80 to 130 mL,¹⁵ and the normal left ventricular end-diastolic volume index is 55 to 65 mL/m².¹⁵ Left ventricular end-diastolic area measured in the left parasternal short-axis view at the level of the midpapillary muscle is commonly used to estimate volume status (Fig. E2-8). The normal values for left ventricular end-diastolic area in the short-axis view are 9.5 to 22 cm².¹⁵

Two-dimensional TTE evaluation of ventricular dimensions has been found to be useful in assessing preload and optimizing therapy of ICU patients.^{25,70} Nevertheless, image quality may be suboptimal and preclude adequate visualization of the endocardial border by TTE. This potential limitation of TTE has been partly circumvented in recent years with the advent of harmonic imaging and contrast echocardiography (see later). In cases in which endocardial border visualization remains suboptimal, TEE is the modality of choice. With TEE, left ventricular volume can be estimated rapidly by subjective assessment of the left ventricular size. Quantitatively, it is estimated

FIGURE E2-8 ■ Calculation of left ventricular end-diastolic area in the transthoracic short-axis view at the level of the midpapillary muscle by endocardial contour tracing. Values of normal left ventricular end-diastolic area in the short axis range from 9.5 to 22 cm².¹⁵ The level of the midpapillary muscle is used because of the reproducibility of the view and because changes in left ventricular volume affect the short axis of the ventricle to a greater degree than the long axis. LV, left ventricle; RV, right ventricle.

most often by determining left ventricular cross-sectional area at the end of diastole, most commonly using the transgastric short-axis view at the level of the midpapillary muscle. This section is used because of the reproducibility of the view and because changes in left ventricular volume affect the short axis of the ventricle to a greater degree than the long axis.¹⁴ The end-diastolic area must be measured consistently from the same reference section. End-diastolic area measured with TEE correlates with left ventricular volume determined by radionuclide studies.⁷⁰

Systolic obliteration of left ventricular cross-sectional area accompanies decreased end-diastolic area and is considered to be a sign of severe hypovolemia (Fig. E2-9). Although a small end-diastolic area generally indicates hypovolemia, a large end-diastolic area does not indicate adequate preload in patients with left ventricular dysfunction. Also, when systemic vascular resistance is low, as in early sepsis, left ventricular emptying is improved because of the lowered afterload. In these situations, it may be difficult to differentiate hypovolemia from low systemic vascular resistance by echocardiography alone, because both conditions are associated with decreased end-diastolic area. Knowledge of left ventricular end-diastolic volume or absolute preload does not allow for accurate prediction of the hemodynamic response to alterations in preload.⁷¹ Tousignant et al.⁷² investigated the relationship between left ventricular stroke volume and left ventricular end-diastolic area in a cohort of ICU patients and found only a modest correlation ($r = 0.60$) between single-point estimates of left ventricular end-diastolic area and responses to fluid loading. Based on the assumption that changes in end-diastolic area occur because of changes in left ventricular volume, the determination of this area and its subsequent degree of variation after a fluid challenge could help better assess preload responsiveness. Studies have shown that changes in end-diastolic area measured by TEE using endocardial border tracing are closely related to changes in cardiac output and are superior to measurements of pulmonary artery occlusion pressure for predicting the ventricular preload associated with maximal cardiac output.⁷³

FIGURE E2-9 ■ Systolic obliteration of the left ventricle (LV) in a patient with severe left ventricular hypertrophy and dehydration. This transthoracic parasternal short-axis view shows the left ventricle at end diastole (**A**) and at end systole (**B**). Nearly complete obliteration of the left ventricular cavity is seen at end systole. Systolic obliteration of the cross-sectional area accompanies decreased end-diastolic area and is considered to be a sign of severe hypovolemia. In this case, the patient presented with hypotension and was found to be severely dehydrated because of a viral gastroenteritis. RV, right ventricle.

Circulating volume status also can be assessed by 2D echocardiography by indirectly estimating right atrial pressure; this is often done by assessing the diameter and change in caliber with inspiration of the inferior vena cava (Fig. E2-10). This method has been shown to discriminate reliably between right atrial pressures less than 10 mm Hg or greater than 10 mm Hg.⁷⁴ A dilated vena cava (diameter >20 mm) without a normal inspiratory decrease in caliber (>50% with gentle sniffing) usually indicates elevated right atrial pressure. In mechanically ventilated patients, this measure is less specific because of a high prevalence of inferior vena cava dilation.^{75,76} A small vena cava reliably excludes the presence of elevated right atrial pressure in these patients.^{75,76}

Doppler Flow Patterns. Information obtained by analysis of the Doppler signal at the level of the mitral valve and pulmonary vein offers additional information about preload.^{77,78} These Doppler profiles can be obtained by either TTE or TEE. Transmitral parameters that have been studied include the relation of early to late transmitral diastolic filling (E/A ratio), isovolumetric relaxation time, and the rate of deceleration of early diastolic inflow (deceleration time).¹

A decrease in preload causes a significant reduction in the E wave (early filling flow wave) velocity at the mitral level in conjunction with a decrease of the S wave (systolic flow wave) in the pulmonary vein. In clinical practice, the E/A ratio is easy to assess; the normal value of this ratio is approximately 1.^{1,3} In conjunction with normal left ventricular contractility, a low E/A ratio is usually a characteristic sign of inadequate preload.⁷⁹

Pulmonary venous flow also can be used to assess left atrial pressure. A normal pulmonary venous flow pattern showing a predominance of flow during systole (S phase) compared with early diastole (D phase) usually indicates that left atrial pressure is less than 8 mm Hg, whereas the opposite predominance of flow (in the absence of significant mitral regurgitation) usually indicates elevation of left atrial pressure.¹

Transmitral and pulmonary vein Doppler patterns strongly depend on intrinsic and external factors and are not affected purely by the loading conditions of the left ventricle. It is crucial that interpretation of Doppler parameters be done in conjunction with a global analysis of cardiac function and other available hemodynamic or anatomic variables.

FIGURE E2-10 ■ Indirect assessment of circulating volume status on two-dimensional echocardiography by assessing the diameter and change in caliber with inspiration of the inferior vena cava (IVC). This method has been shown to discriminate reliably between right atrial pressures of less than or greater than 10 mm Hg. A dilated vena cava (>20 mm) without the normal inspiratory decrease in caliber (>50% on gentle sniffing) usually indicates elevated right atrial pressure. A small vena cava reliably excludes elevated right atrial pressure in these patients. In this case, the IVC was dilated at 2.5 cm with minimal respiratory variation in a patient spontaneously breathing. The right atrial pressure was estimated to be approximately 10 to 15 mm Hg. Images were obtained in the subcostal view. HV, hepatic veins; RA, right atrium.

FIGURE E2-11 ■ Systolic anterior motion (SAM) of the mitral valve in a patient with asymmetric left ventricular hypertrophy and dehydration. Two-dimensional transthoracic apical long-axis view shows movement of the anterior leaflet of the mitral valve (arrow) toward the interventricular septum during systole (A). This creates a subaortic dynamic obstruction. The resulting high velocity and turbulence in the left ventricular outflow tract (LVOT) gives a “mosaic” pattern of flow on color Doppler (B). A variable degree of asymmetric mitral regurgitation (MR) also may be present secondary to the systolic anterior motion, as shown in this example. LA, left atrium; LV, left ventricle; RV, right ventricle.

Hypovolemia in the Intensive Care Unit

Precise and rapid assessment of volume status is crucial when caring for hemodynamically unstable ICU patients. Hypovolemia is one of the most common causes of hypotension in the ICU. As was discussed in detail earlier, bedside echocardiography offers a quick and reliable way of estimating volume status by evaluating cardiac dynamics and left ventricular dimensions and area. The finding of end-systolic cavity obliteration is usually a reliable sign of hypovolemia. Other changes in the volume status are usually associated with subtle changes in left ventricular cavity size, so only this extreme is reliable to make the diagnosis of hypovolemia by echocardiography. In general, TTE has good sensitivity for diagnosing the presence of a small hyperdynamic left ventricle, the most typical finding in hypovolemic patients with underlying normal cardiac function, although TEE is useful in the immediate postoperative setting (Video E2-1).

When dynamic left ventricular obstruction is present, cardiac output is low, and even in the presence of marked hypovolemia, pulmonary artery occlusion pressure is high. Paradoxical worsening of hypotension after intravascular volume loading may be the first clue to dynamic left ventricular obstruction in critically ill patients. It is important that this entity be recognized early and that the pathophysiologic process be well understood, because inadequate management of this condition can lead rapidly to worsening of hemodynamic status and death. Dynamic obstruction of the left ventricle can present in different forms. One of these forms is dynamic left ventricular outflow tract obstruction. Although dynamic left ventricular outflow tract obstruction is often seen in association with asymmetric septal hypertrophy, it also can occur in other situations.^{80,81} Dynamic left ventricular outflow tract obstruction is thought to be caused by the Venturi effect. This effect results when excessive acceleration of blood through a conduit produces a decrease in pressure. In the left ventricular outflow tract, such a decrease in pressure leads to a suction phenomenon that draws the anterior mitral leaflet and chordae inward toward

the interventricular septum.⁸² This systolic anterior motion of the mitral valve leads to contact between the mitral leaflet and the septum that creates an obstructive subaortic pressure gradient and distortion of the mitral valve leaflet coaptation (Fig. E2-11).⁸² By 2D echocardiography, the left ventricle appears to be small and hyperdynamic, and there is motion of the anterior leaflet (or chordae or both) toward the septum in systole (see Fig. E2-11). With color Doppler, a “mosaic” pattern of flow is seen in the left ventricular outflow tract, owing to the high velocity and turbulence. Variable degrees of asymmetric mitral regurgitation also may be present (see Fig. E2-11). Continuous-wave Doppler shows the presence of a significant gradient in the left ventricular outflow tract. Dynamic left ventricular obstruction also can be present without systolic anterior motion. In the presence of reduced afterload, dehydration, or significant catecholaminergic stimulation, patients with a small hypertrophied left ventricle (typically seen in elderly patients with chronic hypertension) can develop midventricular obstruction due to hyperdynamic systolic obliteration of the left ventricular cavity (see Fig. E2-9).⁸³ These physiologic factors may predict the development or worsening of left ventricular dynamic obstruction. Interplay of these factors with preexisting ventricular hypertrophy predisposes the patient to develop cardiogenic shock from this combined loss of preload and presence of dynamic left ventricular obstruction. Dynamic left ventricular obstruction has also been described in patients with acute myocardial infarction, mostly in association with apical infarction.^{81,84,85}

In a study by Chenzbraun et al.⁸⁵ in ICU patients, four patients with hemodynamic instability were found to have a small hyperdynamic ventricle on TEE. Of these four patients, three had pulmonary artery occlusion pressure greater than 20 mm Hg. A study by Poelaert et al.²⁰ that evaluated the diagnostic value of TEE compared with pulmonary artery catheterization showed that pulmonary artery catheterization failed to diagnose the presence of hypovolemia in 44% of patients when TEE showed systolic obliteration of the left ventricular cavity, supporting a diagnosis of hypovolemia. TTE and TEE have

been shown to play a key role in making the diagnosis of hypovolemia and left ventricular dynamic obstruction, leading to a dramatic impact on therapy.^{19,21,22,82-85}

Assessment of Pulmonary Artery Pressure

Pulmonary hypertension is common in critically ill patients and is a manifestation of various pulmonary, cardiac, and systemic processes. Pulmonary hypertension is said to be present when systolic pulmonary pressure is greater than 35 mm Hg, diastolic pulmonary pressure is greater than 15 mm Hg, and mean pulmonary pressure is greater than 25 mm Hg.⁵⁹ Many echocardiographic methods have been validated for noninvasive estimation of pulmonary artery pressure.^{59,86} These methods can be helpful in the ICU. Systolic and diastolic pulmonary artery pressures are determined from the tricuspid and pulmonary regurgitation velocities (some degree of regurgitation is essential to be able to obtain a Doppler signal and subsequently determine pulmonary artery pressure). Tricuspid regurgitation is present in more than 75% of healthy adults⁵⁹ and in approximately 90% of critically ill patients.⁸⁷ Peak tricuspid regurgitation velocity, usually obtained by continuous wave Doppler from the right ventricular inflow or the apical four-chamber view position, reflects the pressure difference during systole between the right ventricle and the right atrium (Fig. E2-12).⁸⁸⁻⁹⁰ Peak systolic pulmonary artery pressure is determined from the peak tricuspid regurgitation Doppler velocity using the modified Bernoulli equation⁹¹: $\Delta P = 4 \times (\text{peak tricuspid regurgitation velocity})^2$. To this peak systolic pressure gradient between right ventricle and right atrium is added the estimated right atrial pressure (see previous section) to obtain the peak right ventricular systolic pressure. In the absence of pulmonic stenosis or right ventricular outflow obstruction, peak right

ventricular systolic pressure is equal to systolic pulmonary artery pressure (see Fig. E2-12). Echocardiography also can determine diastolic pulmonary artery pressure by applying the modified Bernoulli equation using the regurgitant Doppler velocity of the pulmonary valve to obtain the gradient between the pulmonary artery and the right ventricle at end diastole. To this is added the estimated right atrial pressure (equivalent to right ventricular end-diastolic pressure in the absence of tricuspid stenosis) to obtain end-diastolic pulmonary artery pressure: end-diastolic pulmonary artery pressure = $4 \times (\text{peak pulmonary regurgitation velocity})^2$ + estimated right atrial pressure. Approximately 70% of critically ill patients have an adequate Doppler signal of pulmonic insufficiency for this calculation.⁹² Tricuspid and pulmonary regurgitation are present at the same time in more than 85% of subjects.⁹³

Assessment of Valvular Function and Integrity

Attention has been drawn to the limitations of the physical examination for the detection of cardiovascular abnormalities.^{94,95} This problem is enhanced in acutely ill patients in the ICU, and many cardiovascular abnormalities may be concurrent with noncardiac illness without being clinically suspected.⁹⁶ Significant valvular abnormalities are a good example of such cardiovascular pathologies that can be present in a critically ill patient without being clinically recognized.⁹⁶ Even in the presence of invasive monitoring, significant valvular pathologies may be missed. Precise evaluation of the valvular apparatus often may be warranted in the ICU. The most common indications for bedside echocardiography for evaluation of valvular apparatus in this patient population are for suspected endocarditis,^{8,24} acute aortic or mitral valve regurgitation,^{97,98} and prosthetic valve dysfunction.¹⁶

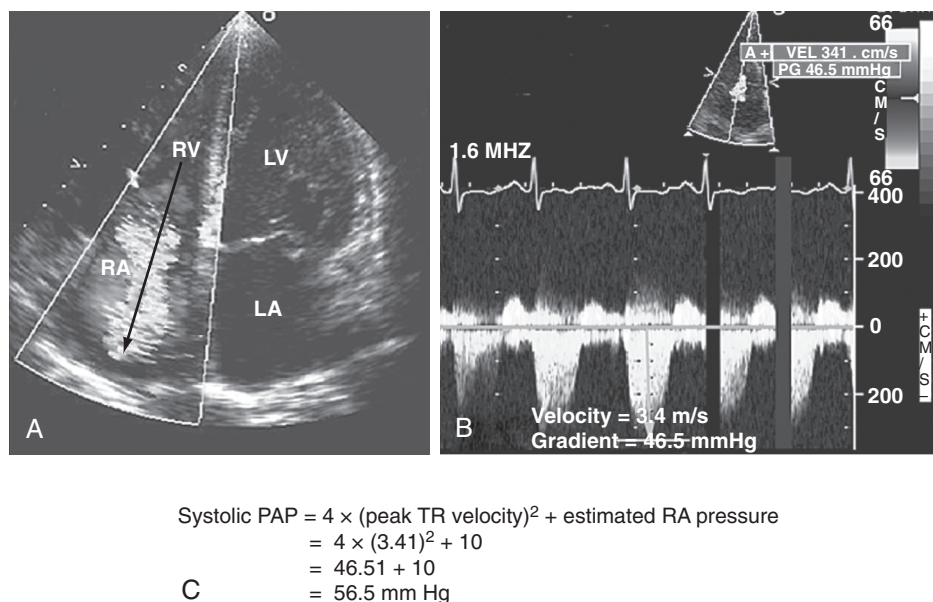

FIGURE E2-12 ■ Calculation of systolic pulmonary artery pressure (PAP). **A**, Color Doppler transthoracic apical four-chamber view showing a significant tricuspid regurgitation (TR) jet from right ventricle (RV) to right atrium (RA). The peak tricuspid regurgitation velocity is measured by placing the continuous wave Doppler in the center of the tricuspid regurgitation jet (arrow). **B**, Spectral continuous wave Doppler profile of the tricuspid regurgitation jet. Peak tricuspid regurgitation velocity (3.41 m/s) and peak systolic pulmonary artery pressure gradient (46.5 mm Hg) can be obtained with this modality. **C**, Peak systolic pulmonary artery pressure also can be determined from the peak tricuspid regurgitation Doppler velocity using the modified Bernoulli equation: $\Delta P = 4 \times (\text{peak tricuspid regurgitation velocity})^2$. To this peak systolic pressure gradient between right ventricle and right atrium is added the estimated right atrial pressure (determined to be 10 in this example) to obtain the peak right ventricular systolic pressure. In the absence of pulmonic stenosis or right ventricular outflow obstruction, peak right ventricular systolic pressure is equal to systolic pulmonary artery pressure. LA, left atrium; LV, left ventricle.

Echocardiography is uniquely suited to the evaluation of valvular heart disease because of its ability to provide information regarding the etiology and severity of valvular lesions. In the ICU, TTE can provide valuable information concerning valvular integrity and function,¹⁶ but it may be suboptimal and not sensitive enough to detect endocarditis, a dysfunctional mitral valve, or prosthetic valve dysfunction. TEE is often warranted. TEE is especially important for the fine detail of mitral valve pathology, such as a torn chordae tendinae and flail scallop (Video E2-2).

Valvular Regurgitation and Prosthetic Valve Dysfunction

In a patient with unexplained hemodynamic instability and a grossly normal TTE examination, performance of subsequent TEE is important to rule out the presence of significant undetected valvular pathology. Common valvular pathologies that can be missed are mitral regurgitation and prosthetic valve dysfunction. In some situations, TTE may provide better imaging than TEE for evaluation of anterior structures such as the aortic valve (native or prosthetic) and for Doppler measurements. TEE is clearly superior to TTE for evaluation of mitral valve pathologies (native and prosthetic). In a study of ICU patients by Alam,¹⁶ TTE compared with TEE was shown either to miss or to underestimate the severity of regurgitation of St. Jude and bioprosthetic valves in the mitral but not in the aortic position.

With acute severe mitral regurgitation, the diagnosis may be clinically difficult because the murmur is often of short duration and low intensity (because of rapid pressure equalization between the left ventricle and the relatively noncompliant left atrium). By TTE, the size of the regurgitant jet in acute mitral regurgitation may appear small and lead to underestimation of severity.⁹⁹ Because of its close anatomic proximity, TEE provides a much more precise evaluation of the degree of mitral regurgitation (Fig. E2-13) and provides crucial diagnostic information regarding the cause for mitral regurgitation. The diagnosis of acute mitral regurgitation represents a medical emergency that may necessitate urgent surgery, so the threshold to perform a TEE when this entity is suspected should be low.^{8,10,97} Also, several investigators have confirmed the superior accuracy, sensitivity, and reliability of TEE over TTE for dysfunction of mitral prostheses, in which ultrasonic shadowing of the left atrium often occurs with the standard transthoracic studies.¹⁰⁰⁻¹⁰³ TEE may be especially useful to detect obstruction of prosthetic valves from thrombus (Video E2-3).

FIGURE E2-13 ■ Severe mitral regurgitation (MR). Transesophageal five-chamber view shows severe mitral regurgitation with a large regurgitant jet (arrow) going far posteriorly in the left atrium (LA). In this case, systolic flow reversal in the pulmonary veins (another echocardiographic sign of severe mitral regurgitation) also was present (not shown on this picture). Because of its close anatomic proximity, transesophageal echocardiography is an excellent tool for the precise evaluation of the degree of mitral regurgitation. LV, left ventricle; RA, right atrium; RV, right ventricle.

Traumatic Valvular Injuries

Traumatic valvular injuries associated with myocardial injury may present as acute regurgitation. Bedside exclusion of major trauma to the aorta, valves, and myocardium is important in the posttrauma context.^{104,105} Valvular injuries may occur as a consequence of blunt or penetrating trauma. Most frequently the aortic valve is injured; less commonly the mitral and tricuspid valves are injured.¹⁰⁶ Valvular dysfunction is usually due to a torn leaflet or rupture of a papillary muscle or chordae.¹⁰⁶ In trauma patients, TEE is the bedside imaging modality of choice to detect these pathologies.^{104,105} In a study by Chirillo et al. assessing the usefulness of TTE and TEE in the recognition and management of cardiovascular injuries after blunt chest trauma, TTE provided suboptimal imaging in 62% of patients, and the bad quality of images obtained was the main cause for the low sensitivity of TTE compared with TEE.

Evaluation of the Pericardial Space

Echocardiography is an essential instrument for the diagnosis of pericardial disease. In the ICU, the most common clinical indication for assessment of the pericardial space is suspected tamponade. The pericardium is a potential space that can become filled with fluid, blood, pus, or uncommonly, air. Presence of fluid in this space is detected as an echo-free space. Pericardial fluid usually is detected easily with TTE. The parasternal long-axis and short-axis views and the apical views usually reveal the effusion (Fig. E2-14). In many critically ill patients with suboptimal TTE image quality, the subcostal view is often the only adequate window available to detect the presence of a pericardial effusion. In these ICU patients with poor acoustic windows and in the post-cardiac surgical setting, TEE may be needed to assess the pericardial space adequately.

FIGURE E2-14 ■ Large pericardial effusion. Transthoracic parasternal short-axis view shows a large, predominantly echo-free space around the left ventricle (LV). This space represents fluid in the pericardium. In this case, the large circumferential pericardial effusion was bloody at pericardiocentesis. Particulate matter (e.g., fibrin and clots) can be visualized as denser echoes around the heart and floating in the effusion.

In addition to assisting in the diagnosis of pericardial effusion and tamponade, 2D echocardiography can assist in its drainage, as pericardiocentesis can be performed safely under 2D echocardiographic guidance.^{107,108} By determining the depth of the effusion and its distance from the site of puncture, it is possible to optimize the needle placement. Echocardiography also can be used for immediate monitoring of the results of the pericardiocentesis.

Cardiac Tamponade in the Intensive Care Unit

The most common causes of cardiac tamponade in the ICU are listed in **Box E2-5**. Echocardiographic 2D signs of tamponade are a direct consequence of increased pericardial pressure, leading to diastolic collapse of one or more cardiac chambers (usually on the right side first) (**Fig. E2-15**). Usually, collapse of the right ventricular free wall is seen in early diastole, and right atrial wall collapse is seen in late diastole.¹⁴ This latter sign is sensitive but not specific for tamponade. It is, however, specific for a hemodynamically significant effusion if the right atrial collapse lasts longer than one-third of the R-R interval.^{14,109} In the presence of a massive effusion, the heart may have a “swinging” motion in the pericardial cavity. This finding is not always present in cardiac tamponade, because the amount of fluid in the pericardial space may be small but still cause a tamponade physiology, depending on the acuity with which the effusion accumulates and the compliance of the pericardium. In poststernotomy patients, tamponade may be missed by TTE (even in cases in which imaging quality seems adequate) because hematomas causing selective cardiac chamber compression

are often in the form of loculated clots located in the far field of the ultrasound beam in the posterior heart region (even when the anterior pericardium is left open).¹¹⁰ The right atrium and right ventricle may be spared in such cases secondary to postoperative adhesions or tethering of the right ventricle to the chest wall anteriorly.¹¹⁰

Another (indirect) sign of a hemodynamically significant pericardial effusion on 2D imaging is plethora of the inferior vena cava with blunted respiratory changes.¹ The latter sign is less valuable in mechanically ventilated patients, because they often have a stiff, dilated inferior vena cava even in the absence of a pericardial effusion (Video E2-4).

Doppler findings of cardiac tamponade are based on characteristic changes in intrathoracic and intracardiac hemodynamics that occur with respiration. Because of the principle of ventricular interaction, mitral inflow velocity (E wave) decreases after inspiration and increases after expiration. Reciprocal changes occur with respect to tricuspid inflow velocity. With tamponade, the exaggerated inspiratory-expiratory variation of the inflow velocity (E wave) over one respiratory cycle should be greater than 40% on the left and greater than 80% on the right.¹¹¹ In critically ill patients, however, mechanical ventilation, bronchospasm, significant pleural effusion, and respiratory distress can alter intrathoracic and intracardiac hemodynamics and make these Doppler findings less reliable. A significant pleural effusion sometimes causes significant respiratory Doppler variations of the inflow velocities that disappear when the effusion is drained.¹¹² The presence of arrhythmia also makes the Doppler findings difficult to interpret. In some circumstances, echocardiographic signs of tamponade may be subtle or absent, so one must keep in mind that the diagnosis of tamponade remains a clinical one and that the echocardiographic signs must be analyzed in conjunction with the clinical findings.

BOX E2-5

Most Common Causes of Cardiac Tamponade in the Intensive Care Unit

- Myocardial or coronary perforation secondary to catheter-based intervention (i.e., after intravenous pacemaker lead insertion, central line placement, or percutaneous coronary interventions)
- Compressive hematoma after cardiac surgery
- Proximal ascending aortic dissection
- Blunt or penetrating chest trauma
- Complication of myocardial infarction (e.g., ventricular rupture)
- Uremic or infectious pericarditis
- Pericardial involvement by metastatic disease or other systemic processes

Complications After Cardiac Surgery

Bedside echocardiography has proved to be of particular value in the critical care management of patients with hemodynamic instability after cardiothoracic operations.^{7,8,83,113-115} TTE is often severely limited in this group of patients.^{5,8} TEE is the modality of choice in this setting because it provides detailed information that can help determine the cause of refractory hypotension. The most frequent echocardiographic diagnoses encountered in these patients are left ventricular or right ventricular failure, tamponade, hypovolemia, and valvular dysfunction. Schmidlin et al.¹¹⁶ studied 136 patients after cardiac surgery and

FIGURE E2-15 ■ Cardiac tamponade. Transesophageal four-chamber view (**A**) shows the presence of a large effusion that severely compresses the right atrium (RA) and right ventricle (RV), which appear slitlike. The left ventricle (LV) also is small because of indirect compression and underfilling. Transgastric short-axis view (**B**) of the same patient shows the large pericardial effusion and severely compressed ventricular chambers. This postcardiotomy patient was in profound shock and was brought back to the operating room emergently for reexploration and drainage of the effusion. LA, left atrium.

showed that a new diagnosis was established or an important pathology was excluded in 45% of patients undergoing TEE. A therapeutic impact was found in 73% of cases. The main indications for TEE in this study were control of left ventricular function (34%), unexplained hemodynamic deterioration (29%), suspicion of pericardial tamponade (14%), cardiac ischemia (9%), and “other” (14%). Reichert et al.¹¹³ performed TEE in hypotensive patients after cardiac surgery. Left ventricular failure was found in 27% of patients, hypovolemia in 23%, right ventricular failure in 18%, biventricular failure in 13%, and tamponade in 10%. Comparison with hemodynamic parameters showed agreement on diagnosis (hypovolemia versus tamponade versus cardiac failure) in only 50% of the cases. Echocardiography identified two cases of tamponade and six of hypovolemia that were not suspected based on standard hemodynamic data. In five patients with hemodynamic findings suggesting tamponade, unnecessary reoperation was prevented because TEE ruled out this diagnosis. Costachescu et al.²² also showed the superiority of TEE compared with conventional monitoring with pulmonary artery catheterization in diagnosing and excluding significant causes of hemodynamic instability in postoperative cardiac surgical patients.

Descriptions of the echocardiographic findings of left ventricular dysfunction, tamponade, hypovolemia, and valvular dysfunction were described earlier in this chapter.

Infective Endocarditis

Occurrence of infective endocarditis in patients hospitalized in an ICU is common. It is often in the differential diagnosis of febrile patients in the ICU. Infective endocarditis was the second most common indication for performance of an echocardiogram among centers reporting their experience, as summarized in a review article by Heidenreich.⁵ Nearly all critically ill patients are at risk for iatrogenic infection, bacteremia, and subsequent endocarditis because of the presence of multiple indwelling catheters, severe underlying diseases, malnutrition, and prolonged mechanical ventilation. Classic clinical findings suggesting endocarditis¹⁰⁶ are uncommon in this patient population. Echocardiography is the test of choice for the noninvasive diagnosis of endocarditis. Fowler et al.¹¹⁷ studied patients with *Staphylococcus aureus* bacteremia referred for TEE and showed that endocarditis ultimately was diagnosed in 25%. Only 7% of these patients had physical findings suggesting endocarditis before TEE. Absence of clinical stig-

mata is especially likely if the infection presents acutely. Because the consequences of untreated endocarditis are devastating and often ultimately fatal, it is important that the infection and its complications be recognized promptly and treated appropriately.⁵⁹

The echocardiographic features typical for infective endocarditis are^{59,118} (1) an oscillating intracardiac mass on a valve or supporting structure or in the path of a regurgitant jet or an iatrogenic device, (2) abscesses, (3) new partial dehiscence of a prosthetic valve, or (4) new valvular regurgitation. Sensitivity for the echographic diagnosis of endocarditis is 58% to 62% for TTE and 88% to 98% for TEE.^{119,120} TEE is particularly useful for detecting small vegetations¹²¹ and detecting vegetations on prosthetic valves. TEE also has been shown to be superior to TTE for diagnosing complications of endocarditis such as aortic root abscess, fistulas, and ruptured chordae tendineae of the mitral valve.¹⁶ Among ICU patients, sensitivity of TTE for the diagnosis of endocarditis is often poor because the quality of the transthoracic study is commonly suboptimal. The sensitivity of TEE for suspected infective endocarditis usually is excellent in the ICU (Fig. E2-16). In a study by Font et al.,⁹⁷ a search for vegetations was the indication for 51 (46%) of 112 TEE studies performed for critically ill patients. TEE increased the detection rate by 27% compared with TTE. Suspicion of endocarditis represented 29% of the indications for TEE in a study of ICU patients by Chenzbraun et al.⁸⁵; 9 (27%) of 31 patients with suspected infective endocarditis had a positive study for endocarditis. All positive studies were in patients who had an increased likelihood for infective endocarditis before the examination, as indicated by the presence of fever, positive blood cultures, new-onset murmur, prosthetic valve, or new-onset heart failure (alone or in combination). None of the patients with native valves and no clinical features of endocarditis had a TEE study diagnostic of infective endocarditis, and in none of them was the diagnosis of infective endocarditis made later. The findings from this study indicate that TEE is not useful as a screening procedure for infective endocarditis in septic patients without high clinical likelihood for endocarditis. The clinical probability of endocarditis should guide the use of TEE. Clinical risk factors considered high risk included intracardiac prosthetic material, positive blood cultures (in particular, *S. aureus*), evidence of peripheral emboli, and history of previous endocarditis^{8,16} (Video E2-5).

As concluded by Colreavy et al.,⁸ performance of TEE in the ICU for suspicion of infective endocarditis should be (1) for cases associated with a clinical likelihood of endocarditis and a negative TTE

FIGURE E2-16 ■ Infective endocarditis of the aortic valve. A 55-year-old patient was admitted to the ICU with fever, chills, hypotension, and respiratory distress for which he had to be intubated. He had 4/4 positive blood cultures for *Staphylococcus aureus*. Transthoracic echocardiography was performed initially, but the quality was suboptimal, and no definite conclusion could be reached. Subsequent transesophageal echocardiography revealed a large vegetation on the left aortic coronary cusp as seen in the midesophageal view at 120 degrees (**A**). Color Doppler examination (**B**) revealed the presence of associated severe aortic regurgitation (AR). The patient was treated with antibiotics and emergent aortic valvular surgery. LA, left atrium; LV, left ventricle.

examination, (2) for suspected prosthetic valve endocarditis, (3) for assessment of complications in known cases of endocarditis, and (4) for cases of *S. aureus* bacteremia when the source is unknown or blood cultures remain positive despite antibiotic therapy. When assessing a patient for infective endocarditis by echocardiography, one must keep in mind the noninfectious causes of vegetations that may result from tumors, myxomatous degeneration, marantic endocarditis, Lambli's excrescences, valve thrombus, and suture material in patients with repaired native or prosthetic valves.

Assessment of the Aorta

In the ICU, use of bedside echocardiography for assessment of suspected aortic pathologies provides many advantages over CT or aortography: there is no need for IV contrast administration, there may be less time delay, there is no need for transportation of a critically ill patient, and cardiac morphology and function can be evaluated at the same time.³ For many years, aortography has been the gold standard for the investigation of suspected injuries of the aorta.³ The advent of noninvasive modalities such as CT, magnetic resonance imaging (MRI), and TEE with their excellent sensitivity and specificity to diagnose aortic pathologies has decreased the need for aortograms.

Suspected aortic pathologies can be encountered in different ICU settings. The aorta may have to be imaged to rule out dissection, rupture, aneurysm, aortic debris, or aortic abscess. TTE is a good initial imaging modality for evaluation of the proximal aorta (ascending aorta and arch),⁵⁹ but the descending thoracic aorta cannot be adequately assessed and visualized with this modality. Because of the close anatomic relationship between the thoracic aorta and the esophagus, TEE allows optimal visualization of the entire thoracic aorta (Fig. E2-17). As described earlier, there exists a blind spot in the distal portion of the ascending aorta and the proximal portion of the transverse aorta where imaging can be suboptimal.^{122,123}

Aortic Dissection and Rupture

Patients presenting with suspected aortic dissection need emergency diagnosis and treatment. Different noninvasive tests have been advocated for evaluation of suspected aortic dissection, including TEE, CT, and MRI.^{5,124} Nienaber et al.¹²⁴ compared all three modalities and found that they had similar sensitivities (98%). MRI had higher specificity than TEE (98% vs. 77%). A limitation of the study was that

single-plane TEE was used. With multiplane TEE, specificity is improved to greater than 90% (see Fig. E2-17).¹²² TTE was compared with CT and aortography in a multicenter European cooperative study,¹²⁵ and it was shown that TEE was superior compared with both modalities for the diagnosis of aortic dissection (sensitivity 99%). Other studies have confirmed the high accuracy of TEE.¹²⁵⁻¹²⁸ A negative TEE examination for the diagnosis of aortic dissection, even in a high-risk population, has high negative predictive value.¹²⁹ Most centers utilize contrast CT scanning as the first choice for suspected aortic dissection, but TEE is an option in patients who cannot receive contrast, such as those who have advanced renal disease or are too unstable to be transported to the CT scanner (Video E2-6).

Another common indication to perform emergency aortic imaging in the ICU is assessment of patients with blunt or penetrating chest trauma.³ These patients are at high risk of life-threatening aortic injuries such as traumatic dissection and rupture, and prompt diagnosis and treatment are critical. Exclusion of major trauma to the ascending and descending aorta at the bedside is important in this context.¹⁰⁵ The value of TEE on admission for trauma patients with enlarged mediastinum and hemodynamic instability, with or without a combination of several other symptoms (e.g., pleural effusion, decreasing hematocrit, thoracic vertebral fracture), has been stressed by many authors.¹³⁰⁻¹³³ Patients usually have a contained hematoma around the aortic dissection.¹³¹ Transection of the thoracic aorta usually is seen at the level of the ligamentum arteriosum.

Additional helpful features of TEE in evaluating aortic pathologies are the ability to detect or assess extension of dissection into the proximal coronary arteries; the presence of pericardial hematoma or effusion; the presence, severity, and mechanism of associated aortic valve regurgitation; the point of entry and exit between the true and false lumens; the presence of thrombus in the false lumen; and ventricular function.¹⁶ When TEE findings are equivocal or negative in cases of suspected thoracic aortic disease, other imaging modalities such as aortography, CT, or MRI should still be performed.

Assessment for Intracardiac and Intrapulmonary Shunts

In critically ill patients, clinical suspicion for an intracardiac or intrapulmonary shunt most often is raised in the context of unexplained embolic stroke or refractory hypoxemia. In such cases, the presence of

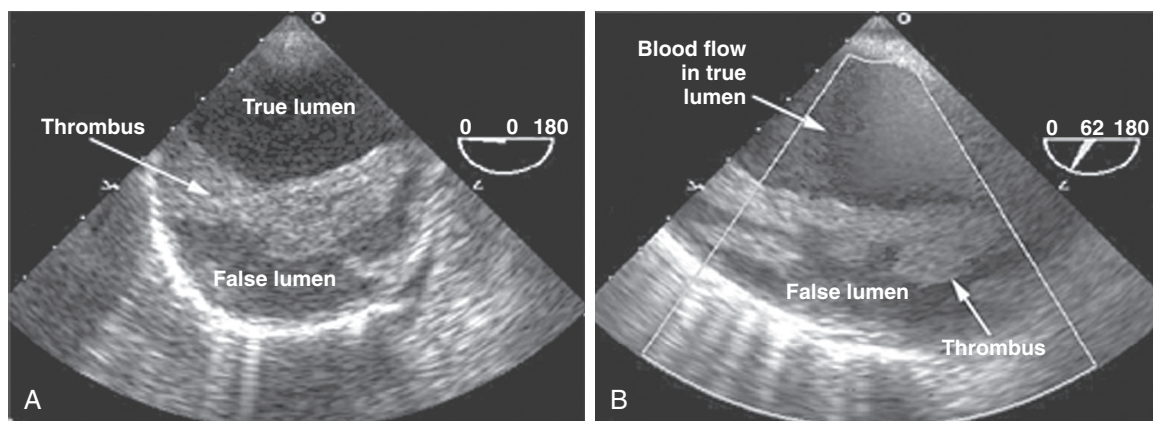

FIGURE E2-17 ■ Dissecting thoracic aortic aneurysm. A 65-year-old patient presented to the emergency department with severe ripping chest pain radiating to the back. The initial electrocardiogram was unremarkable, and the chest x-ray showed a widened mediastinum. The patient underwent transesophageal echocardiography, which revealed the presence of a large dissecting aneurysm of the descending thoracic aorta. The short-axis view (**A**) revealed the presence of a large aneurysm with a true and a false lumen. The false lumen was filled with thrombus (arrow). On the longitudinal view with color Doppler (**B**), blood flow in the true lumen is visualized. The patient was taken emergently to the operating room.

a right-to-left shunt must be excluded. Common origins of right-to-left shunt are atrial septal defect or patent foramen ovale at the cardiac level⁵ and arteriovenous fistula at the pulmonary level.⁵ To be able to detect the presence of such a shunt at the bedside, a contrast study often is needed, because the shunt is usually not well visualized with 2D echocardiography alone. Color-flow imaging increases the detection rate of intracardiac shunt to some extent, but usually only when the shunt is large. Accordingly, a contrast study should be performed routinely as part of a TEE or TTE examination when evaluating a patient with unexplained embolic stroke or refractory hypoxemia in the ICU. For this purpose, agitated saline contrast is usually used. Approximately 0.5 mL of air is mixed with 10 mL of normal saline and is vigorously agitated back and forth between two syringes connected to the patient by a three-way stopcock. After an adequate echocardiographic view of the right and left atrial cavities has been obtained, the agitated saline is forcefully injected IV. After injection, the contrast is seen in the vena cava, right atrium, right ventricle, and pulmonary artery. In the absence of a shunt, only a minimal amount of contrast should be seen in the left-sided cavities, because most of the microbubbles from the agitated saline are unable to pass through the pulmonary capillaries. If an intracardiac shunt is present, such as an atrial septal defect or patent foramen ovale, left-sided contrast is observed immediately after right-sided opacification, and the contrast is seen going through the interatrial septum (Fig. E2-18). Performance of a Valsalva maneuver by the patient during contrast injection increases the sensitivity of the bubble study to detect right-to-left shunting. In mechanically ventilated patients, a maneuver equivalent to a Valsalva may be performed by inducing sudden release of sustained airway pressure previously achieved by inflating the lungs manually. This maneuver reverses the atrial transseptal gradient and may help uncover a patent foramen ovale that would not have been seen otherwise. Right-to-left shunting also can be caused by the presence of pulmonary arteriovenous fistulas. These often are associated with end-stage liver disease (hepatopulmonary syndrome). With this type of shunt, contrast is seen to appear in the left atrium from the pulmonary veins instead of through the atrial septum; this finding is best detected by TEE, which usually permits visualization of all four pulmonary veins. The characteristic of intrapulmonary versus intracardiac shunt is that there is a longer delay (three to five cardiac cycles) between the

appearance of contrast from the right-sided to left-sided cavities in the presence of an intrapulmonary shunt.⁵ Agitated saline is a simple and easy way to use contrast at the bedside.

Other types of intracardiac shunts also can be encountered in the ICU. After myocardial infarction, patients can develop cardiogenic shock due to acute development of a ventricular septal defect and resultant left-to-right shunt. Physical examination and invasive hemodynamic monitoring (pulmonary artery catheterization) sometimes can miss this diagnosis. Echocardiography reveals a disrupted ventricular septum with a high-velocity left-to-right shunt. This kind of shunt usually is well visualized without use of contrast. The diagnosis can be established by 2D and Doppler TTE in approximately 90% of cases.¹³⁴ Penetrating cardiac trauma is often associated with intracardiac and extracardiac shunts, and TEE is becoming the obvious tool for perioperative early identification of occult shunts.¹⁴ Identification of these shunts is paramount in these critically ill patients, because missing them may lead to cardiac tamponade and rapid death. TEE has been shown to be superior to angiography and TTE to visualize these lesions.¹³⁵⁻¹³⁷

Unexplained Hypoxemia

Patent foramen ovale is present in 25% to 30% of healthy individuals.^{59,106} Usually it allows only minimal and intermittent right-to-left shunting. When the right atrial pressure is increased and exceeds left atrial pressure, the patent foramen ovale can widen and significantly increase the importance of the right-to-left shunt, with resultant significant hypoxemia. In a critically ill patient, this increase in right-sided pressure can occur from pulmonary hypertension secondary to acute respiratory distress syndrome or pulmonary embolism, right ventricular failure (from infarction or pulmonary hypertension), or severe tricuspid regurgitation, which is often seen in the ICU for a variety of reasons. In critically ill patients, TEE is in general more useful than TTE for evaluation of patent foramen ovale, atrial septal defect (see Fig. E2-18), and pulmonary arteriovenous fistula¹³⁸ because of the close proximity of the lesion to the ultrasound transducer.

Patients with patent foramen ovale and persistent refractory hypoxemia despite ventilator and hemodynamic manipulation sometimes may need to have catheter-based septal defect closure devices inserted. TEE is crucial to assist in the performance of this procedure.¹³⁹

FIGURE E2-18 ■ Positive bubble study shows the presence of a right-to-left shunt via a patent foramen ovale (PFO). Transesophageal echocardiography was performed in a patient hospitalized in the ICU for pneumonia. He presented with refractory hypoxemia that was out of proportion to the underlying minor pulmonary process. Transesophageal echocardiography was obtained (multiplane transducer at 98 degrees) and showed the presence of a patent foramen ovale with a significant right-to-left shunt due to elevated right atrial pressure. Soon after contrast injection (**A**), the bubbles are seen arriving in the right atrium (RA) from the superior vena cava (SVC). A few seconds later (**B**), a complete opacification of the right atrium is reached, and the bubble contrast is clearly seen shunting through the patent foramen ovale from the right atrium to left atrium (LA).

FIGURE E2-19 ■ Large clot in the left atrial wall and left atrial appendage (LAA). A 72-year-old patient hospitalized in the ICU for urosepsis developed rapid atrial fibrillation. She was initially anticoagulated and rate-controlled. Despite resolution of the septic picture, she remained in atrial fibrillation 4 days after its onset. The patient underwent transesophageal echocardiography before undergoing a planned electrical cardioversion. The midesophageal view with multiplane transducer at 70 degrees revealed the presence of a large clot (3.35×1.45 cm) in the posterolateral wall of the left atrium (LA) extending into the LAA. With these findings, the patient's anticoagulation regimen was intensified, and the cardioversion was not performed. LV, left ventricle.

Source of Embolus

In the setting of acute unexplained stroke, echocardiography often is required to determine whether a potential embolic source of cardiac origin is present. TEE is the modality of choice for this purpose. Possible cardiac sources of emboli to the arterial circulation include left atrial or appendicular thrombus, left ventricular thrombus, thoracic atheromatosis, and right-sided clots (right atrium, right ventricle, vena cava) combined with a right-to-left intracardiac shunt (leading to a paradoxical embolus). Cardiac tumors and vegetations are other potential sources of emboli from cardiac origin that must be considered.

When cardioversion is considered for a critically ill patient with atrial fibrillation or flutter, performance of TEE is helpful in evaluating the left atrium and appendage for the presence of thrombus (Fig. E2-19). If no intracardiac clots are documented, cardioversion can be performed with minimal embolic risks.

USE OF CONTRAST AND HARMONIC TECHNOLOGY TO ENHANCE TRANSTHORACIC EXAMINATIONS WITH POOR IMAGE QUALITY IN A CRITICALLY ILL PATIENT

Using standard echocardiographic methods, endocardial delineation is suboptimal in approximately 30% of cases.¹⁴⁰ However, two developments in ultrasound have improved the quality of endocardial border definition: harmonic imaging and IV contrast echocardiography.¹⁴¹ Dramatic improvements in image quality have been achieved with the development of harmonic imaging. This technology exploits the formation of ultrasound signals that return to the transducer at a multiple of the transmitted (fundamental) frequency, referred to as the *harmonic frequency*.¹ Signals are received by the ultrasound transducer at twice the transmitted frequency. This "second harmonic imaging"

results in images with better contrast between the myocardium and cardiac chambers and improved endocardial definition compared with fundamental imaging.¹⁴²⁻¹⁴⁴ Most current ultrasound equipment includes harmonic imaging as a standard feature.

In critically ill patients with poor acoustic windows, endocardial visualization still may be inadequate despite the use of second harmonic imaging.¹⁴⁰ In these patients, contrast agents capable of producing left ventricular cavity opacification with an IV injection can be helpful in delineating endocardial borders. Several contrast agents are currently available that contain albumin microspheres filled with perfluorocarbon gas, allowing for the passage of contrast through the lungs with appearance of contrast in the left ventricle.¹ The chamber is opacified by the contrast agent within 1 minute of administration and allows improved endocardial border detection. The presence of contrast also enhances Doppler signals.¹⁴⁵ Studies have examined the impact of these newer modalities of harmonic imaging and contrast in the ICU. Reilly et al.¹⁴⁶ assessed the benefits of contrast echocardiography for the evaluation of left ventricular function in 70 unselected ICU patients; 22 patients (31%) were receiving mechanical ventilation. Left ventricular EF could not be obtained at all in 23% of patients with standard imaging, but when harmonic imaging was employed, left ventricular EF was unobtainable in only 13% of patients. When contrast imaging was employed, left ventricular EF was measurable in all the patients. Ejection fraction was confidently determined in 56%, 62%, and 91% of patients with standard imaging, harmonic imaging, and contrast imaging. In this study, contrast imaging was safe and dramatically improved the capacity to evaluate left ventricular EF and regional wall motion reliably compared with fundamental and harmonic imaging. Yong et al.¹⁴¹ extended these observations by comparing the results of harmonic and contrast imaging with an independent standard (i.e., TEE) in 32 consecutive critically ill patients who were considered technically very difficult. Estimation of EF was possible in 31%, 50%, and 97% with fundamental imaging, harmonic imaging, and contrast imaging. Quantification of EF by contrast enhancement correlated best with TEE ($r = 0.91$).

In critically ill patients with suboptimal TTE image quality, contrast echocardiography combined with harmonic imaging provides a non-invasive and safe alternative to TEE for determination of regional and global left ventricular function (Fig. E2-20).¹⁴⁰ It is a rapid and simple technique that can be performed at the bedside in the ICU, with positive impact on interpretation of left ventricular function. Before using TEE, this technique should be considered in critically ill patients when TTE is inadequate for the evaluation of left ventricular function.¹⁴⁰

COMPARISON BETWEEN BEDSIDE ECHOCARDIOGRAPHY AND PULMONARY ARTERY CATHETER IN THE INTENSIVE CARE UNIT

Since its introduction into clinical practice in 1970, pulmonary artery catheterization has been the standard hemodynamic monitoring technique for critically ill patients in the ICU.¹⁴⁷⁻¹⁴⁹ Pulmonary artery catheterization provides clinicians with indices of cardiovascular function to assist in therapeutic decision making. Pulmonary artery catheterization can be a useful diagnostic tool, aiding in the management of critically ill patients. Nevertheless, poor interpretation of the data it provides can lead to excessive morbidity and mortality.^{63,147,150,151} Conventional monitoring using a pulmonary artery catheter has been shown to be limited in the evaluation of global ventricular function,^{19,21} and echocardiographic studies have established that pulmonary artery occlusion pressure often does not allow accurate assessment of left ventricular preload.^{26,152,153} The frequent changes in ventricular compliance and loading conditions occurring in critically ill patients can affect systolic and diastolic function. In such cases, conventional monitoring does not enable early detection of acute changes in function, and it does not allow the clinician to discern systolic from diastolic changes.¹⁹

FIGURE E2-20 ■ Use of contrast agent to improve endocardial border delineation in a critically ill patient with suboptimal transthoracic image quality. A suboptimal transthoracic apical two-chamber view (**A**) of the left ventricle (LV) obtained from a ventilated ICU patient with hemodynamic instability. The poor endocardial resolution makes regional and global ventricular function hard to assess. Same transthoracic two-chamber apical view (**B**) in the same patient after contrast injection. A dramatic improvement in endocardial border definition is noted. Contrast echocardiography combined with harmonic imaging provides a noninvasive, safe alternative to transesophageal echocardiography for determination of regional and global left ventricular function.

In critically ill patients, echocardiography, particularly TEE, has the ability to clarify diagnosis and define pathophysiologic process more precisely than pulmonary artery catheterization. In a prospective study of limited scope, Benjamin et al.²¹ found that TEE-derived data disagreed with the pulmonary artery catheterization evaluation of intracardiac volume in 55% of cases and with the pulmonary artery catheterization assessment of myocardial function in 39% of cases. These authors also showed that the post-pulmonary artery catheterization therapeutic recommendations were different from the post-TEE therapeutic recommendations in 58% of patients. In a retrospective analysis of 108 critically ill patients who underwent a TEE, Poelaert et al.²⁰ found that of 64% of patients with pulmonary artery catheterization, 44% underwent therapy changes after TEE (41% in the cardiac and 54% in the septic subgroup). Also, these investigators found that in 41% of patients without pulmonary artery catheterization, TEE led to a change in therapy. They concluded that TEE produced a change in therapy in at least a third of ICU patients, independent of the presence of pulmonary artery catheterization.²⁰

Another significant advantage of echocardiography in the ICU is the speed with which it can be performed relative to pulmonary artery catheterization. In the study by Benjamin et al.,²¹ TEE was performed in 12 ± 7 minutes versus 30 minutes or more for pulmonary artery catheterization insertion. In a study by Kaul,¹⁵⁴ the average time required to place a pulmonary artery catheter and record the data was 63 ± 45 minutes versus 19 ± 7 minutes to perform bedside TEE. Reported complications of pulmonary artery catheterization include pneumothorax, hemothorax, bacteremia, sepsis, cardiac arrhythmias, pulmonary artery rupture, cardiac perforation, and valvular damage.²¹ Compared with pulmonary artery catheterization, bedside echocardiography has a better safety profile, as reported previously in this chapter.

A major advantage of pulmonary artery catheterization versus TEE is that the catheter can more easily serve as a continuous monitoring technique to assess the response to a therapeutic intervention.²¹ This potential advantage may provide little benefit, however, in patients in

whom the information is misinterpreted or inadequate. In some ICUs, TEE has completely replaced pulmonary artery catheterization for assessment of circulatory status of mechanically ventilated patients.³⁸

Despite having multiple limitations, pulmonary artery catheterization still has a role in the ICU and remains a useful diagnostic tool when used by physicians who have extensive experience with it.^{20,155} A combination of invasive pressure monitoring and TEE probably offers the most complete bedside evaluation of morphology and intracardiac hemodynamics and provides a more precise pressure-volume evaluation of left ventricular and right ventricular function and filling.^{20,22}

IMPACT OF BEDSIDE ECHOCARDIOGRAPHY ON DIAGNOSIS AND MANAGEMENT IN A CRITICALLY ILL PATIENT

Echocardiography often provides unexpected diagnoses in critically ill patients. Compared with TTE and invasive hemodynamic monitoring, TEE frequently provides different or additional information. This information often is important for adequate and optimal adjustment of therapy. Several studies have examined the impact of bedside echocardiography, particularly TEE, on the management of critically ill patients. Published studies have reported changes in management after TEE in 30% to 60% of patients,^{17,20,156,157} leading to surgical interventions in 7% to 30%.^{17,98,157,158} Impact varies depending on the type of ICU population being studied. Several studies have reported the clinical impact of urgent TEE in hemodynamically unstable patients.^{157,159,160} In a prospective study of surgical ICU patients by Bruch et al.,²³ echocardiography altered management in 50 (43%) of 115 patients. Alterations in medical management induced by TEE included administration of fluids and initiation or discontinuation of inotropic agents, anticoagulants, or antibiotics. These findings are similar to findings reported in patients in medical or coronary care ICUs.^{10,158} In a retrospective

study done by Colreavy et al.⁸ of a mixed medical and surgical ICU population, TEE findings led to a significant change in management in 32% of all studies performed. In a prospective study by Heidenreich et al.¹⁶¹ of 61 critically ill patients with unexplained hypotension, new diagnoses not made with TTE were made in 17 patients (28%), leading to surgical intervention in 12 (20%). Prospective randomized trials to study the ultimate impact of bedside echocardiography on mortality and morbidity in the ICU are needed. Such studies would be difficult to do, however, given the growing use and importance of this technology in the critical care setting.

OTHER APPLICATIONS OF BEDSIDE ULTRASONOGRAPHY IN THE INTENSIVE CARE UNIT

Central Line Placement

Central venous catheterization is performed frequently in critically ill patients. Placement of a central venous catheter is not without risk and can be associated with adverse events that are hazardous to patients and expensive to treat.¹⁶²⁻¹⁶⁴ Complications can be seen in 15% to 20% of cases.¹⁶⁵⁻¹⁶⁷ As described in a review by McGee and Gould,¹⁶⁸ complications related to central venous line placement are most often mechanical (arterial puncture, local hematoma, hemothorax, pneumothorax), infectious (catheter colonization and related bloodstream infection), and thrombotic. Complications are influenced by patient factors (obesity, coagulopathy, previous failed catheterization), site of attempted access, and operator experience.¹⁶⁹ As previously reported, only approximately 38% to 65% of patients are cannulated on the first attempt using a blind method.^{170,171}

The use of ultrasound guidance during central venous catheterization has been well shown to reduce the risk of complications, mostly so for the internal jugular route. Ultrasound guidance also speeds catheter placement, decreases the number of attempts before successful placement, and improves the overall rate of successful placement. Ultrasound can be used to help localize and define the anatomy of the vein, with subsequent placement of the central venous catheter by the standard use of anatomic landmarks at the site identified by ultrasound, with the knowledge that a vein is present, patent, and of adequate size. Ultrasound also can be used to provide real-time 2D ultrasound guidance to locate the vein and subsequently introduce the needle through the skin and into the vessel. Multiple studies have reported the superiority of ultrasound-assisted cannulation of the internal jugular vein in ICU patients, compared with the external landmark-guided technique.¹⁷⁰⁻¹⁷² Trials looking at ultrasound guidance after failure by the landmark method reported success rates ranging from 33% to 100%.^{169,173-175} A meta-analysis¹⁷⁵ of the literature comparing guidance using anatomic landmarks only versus guidance using ultrasound for the placement of central venous catheters indicates that ultrasound guidance significantly decreases placement failure by 64%, decreases related complications by 78%, and decreases the need for multiple placement attempts by 40%. Data showing superiority of the ultrasound guidance technique are consistent and strong for the internal jugular vein approach but less so for subclavian venous catheterization.¹⁷⁵⁻¹⁷⁷

Some patients can be identified in whom cannulation may be more difficult or in whom consequences of a complication could be more serious.¹⁶⁹ In these patients (Box E2-6), central venous cannulation may be laborious and risky, and ultrasound guidance should be considered. Hatfield and Bodenham¹⁶⁹ showed the benefit of portable ultrasound when central venous access was difficult. As suggested by this study and others,¹⁷⁸ ultrasound guidance is particularly beneficial when used in difficult cases or when a competent operator fails after a few attempts using surface landmarks.

Ultrasound guidance is useful for operators with varying levels of experience.^{169,175} The technique is easy to learn and can be self-taught with some practical assistance from radiologists or other experienced

BOX E2-6

Criteria for Difficult Central Venous Access

Limited access sites for attempts (e.g., local infection, other catheters present)
 Difficult to identify surface landmarks (e.g., local swelling or deformity, severe obesity)
 Previous complications (e.g., pneumothorax, arterial puncture)
 Previous catheterization difficulties (e.g., multiple sites attempted, failure to gain access, >3 punctures at one site)
 Uncorrected coagulopathy (APTT > 1.5x; INR > 1.8; platelets < 50,000/ μ L)
 Patient unable to tolerate supine position
 Known underlying vascular anomalies

APTT, activated partial thromboplastin time; INR, international normalized ratio.

FIGURE E2-21 ■ Transverse view of normal anatomy of the right internal jugular (RIJ) vein and right common carotid artery (RCCA). Ultrasound examination helps determine the anatomic relationship, size, and patency of the vessels. Knowledge of these important vessel characteristics helps determine if the anatomy is suitable for central vein catheterization at a low risk. If the vessel anatomy is normal and the operator is experienced, subsequent venous catheterization can be done by the surface landmark technique or under real-time ultrasound guidance. If high-risk characteristics are identified (see Box E2-6), however, real-time ultrasound guidance (or selection of a different access site) would be preferred. (Courtesy Dr. Kurian Puthenpurayil.)

sonographers.^{169,179,180} Familiarity with the anatomy and equipment is easy to obtain safely at the bedside.

Most large vessels that are catheterized usually can be imaged by ultrasound. Different types of ultrasound modalities can be used to help guide central vessel cannulation, including 2D ultrasound, Doppler transducer, Doppler with the probe in the needle, and fingertip pulse Doppler. With 2D imaging, fluid such as blood in vessels is black because there is nearly complete transmission of ultrasound.¹⁶⁹ Color Doppler mode helps delineate the flow patterns in vessels. Doppler-only equipment that provides no images has shown equivocal results in studies of vascular access.^{176,181}

With 2D imaging, arteries are characteristically small, pulsatile, and difficult to compress with the probe.¹⁶⁹ Veins are usually larger, are nonpulsatile (except in the presence of severe tricuspid regurgitation), are easily compressible, and distend when the patient is placed with the head down or when a Valsalva maneuver is performed.¹⁶⁹

Vessels can be examined in the transverse and longitudinal views. The transverse view permits identification of the vein and arteries based on the sonographic characteristics mentioned earlier and clarifies their positions relative to one another (Fig. E2-21). The transverse and longitudinal views enable the sonographer to monitor in real time the passage of the needle through the skin and the anterior vessel wall.

FIGURE E2-22 ■ Transverse view of left carotid artery and left internal jugular (IJ) vein. The distance from the skin to the anterior wall of the vein is measured before insertion of a central venous catheter (**A**). Knowledge of this distance prevents the operator from going too deep with the needle when searching for the vein; this helps decrease the incidence of pneumothorax. After insertion, the catheter position in the jugular vein is confirmed (**B**).

FIGURE E2-23 ■ Transverse view of the left carotid and internal jugular (IJ) vein in a spontaneously breathing patient sitting in bed at a 30-degree angle. The patient was febrile and dehydrated. A near-total collapse of the vein (which is of small caliber) can be appreciated on inspiration (**B**) compared with expiration (**A**).

Ultrasound guidance also ensures detailed and accurate control of the needle (Fig. E2-22).¹⁶⁹

During vessel examination, the sonographer specifically should assess the presence and patency of the vein (Fig. E2-23), the distensibility and compressibility of the vein, the position of the vein relative to the surrounding arteries (Fig. E2-24), and the presence of a thrombus in the vein (Fig. E2-25).¹⁶⁹ Ultrasound identification of certain anatomic characteristics such as small vessel size (<5 mm), intraluminal thrombus, and anterior location of the artery relative to the vein helps the physician identify unfavorable vessel anatomy and choose another catheterization site. A study by Levin et al.¹⁸² showed that 2D ultrasound guidance for the insertion of radial artery catheters was easy to use and increased the rate of success of insertion at first attempt. It was determined to be a useful adjunct to arterial catheter insertion. More studies are needed in the use of ultrasound for cannulation of peripheral arterial conduits.

Assessment of Pleural Effusions and Intraabdominal Fluid Collections

In critically ill patients, atelectasis and pleural effusions are frequent and often are present at the same time. Patients in the ICU are most often supine, and chest x-rays performed in this position offer limited

sensitivity for the diagnosis of pleural effusion.¹⁸³ In many instances, neither atelectasis nor infiltration can be differentiated from pleural effusion. An alternative diagnostic method is needed to provide better results. Decubitus chest radiographs may show if fluid is free flowing, but this approach cannot localize or characterize the effusion precisely. CT of the chest shows the amount and distribution of fluid and is superior to plain lateral decubitus films. CT also can differentiate fluid from atelectasis and reveal information about the lung parenchyma. Chest CT requires transport to the radiology suite, however, which can be hazardous in unstable critically ill patients. Ultrasound examination of the pleural space has proved to be valuable for diagnosis of effusion.¹⁸⁴⁻¹⁸⁸ The value of ultrasound for localizing fluid before catheter drainage or simple thoracentesis is well recognized. Ultrasound is especially valuable for localizing loculated or small effusions before a drainage procedure. In mechanically ventilated patients, blind thoracentesis can be hazardous, especially if the effusion is small or if the patient is on a high level of positive end-expiratory pressure.¹⁸⁹ Lichtenstein et al.¹⁸⁹ evaluated the feasibility and safety of ultrasound-aided thoracentesis in 40 mechanically ventilated patients. No complications occurred in the 45 ultrasound-aided thoracenteses, all performed by ICU physicians.

Basic skill required to detect a pleural effusion may be acquired in minutes and improves with experience.¹⁹⁰ In most instances, the pleural

tap does not have to be done under real-time ultrasound guidance. A critically ill patient first must be positioned adequately on the back or on the side. Scanning of the pleural space is performed with the ultrasound probe. The probe must be oriented upward and downward, laterally and medially, and anteriorly and posteriorly so as to obtain a complete anatomic assessment of the area. The pleural fluid is usually hypoechoic and appears black. The surrounding solid structures (soft tissue, diaphragm) and organs (lung, liver, heart, spleen) are visualized as structures with different degrees of echogenicity around the effusion (Fig. E2-26). The presence of aerated lung causes airy artifacts. Ribs usually yield artifactual anechoic images. When the effusion has been well assessed, one must determine the feasibility of safely doing a thoracentesis. One must check for the absence of interposition of

lung, heart, liver, or spleen during the respiratory cycle¹⁸⁹ to avoid puncturing these organs, which potentially can cause catastrophic complications. When an optimal and safe position for thoracentesis has been determined, the skin should be marked and disinfected, and the patient should remain in the exact same position as was used during the ultrasound examination. Optimally, the puncture should be done within seconds to minutes of the marking.

The same diagnostic and therapeutic procedures described earlier can be applied for intraabdominal fluid collections in a critically ill patient. Evaluation for intraabdominal fluid collection or abscess is restricted to areas that are not impeded by gas-filled structures¹⁹¹ and include the regions around the liver and gallbladder, spleen, kidneys and lateral retroperitoneal areas, and pelvis around the uterus and

FIGURE E2-24 ■ Transverse view of left internal carotid artery and left internal jugular (IJ) vein. Notice the relative position of the jugular vein directly overlying the carotid artery. This type of anatomy is common on the left side and, when present, significantly increases the risk of procedure failure or arterial puncture.

FIGURE E2-26 ■ Transverse view of a right pleural effusion. Collapsed atelectatic lung is well visualized “floating” in the effusion. (Courtesy Dr. Kurian Puthenpurayil.)

FIGURE E2-25 ■ Transverse (A) and longitudinal (B) views of the right carotid artery and right internal jugular vein. Complete thrombosis of the right internal jugular (IJ) vein can be appreciated. Notice the small caliber of the thrombosed vein and the increased echogenicity of the thrombotic material within it. The vessel could not be compressed by probe pressure.

bladder.¹⁹¹ Fluid that does not change shape with probe pressure or patient positioning most likely represents a loculated collection.¹⁹¹ Echogenic material and diffuse echoes on ultrasound within a fluid collection suggest the presence of particulate matter (e.g., fibrin or clots) and may represent an exudate or blood collection. As with pleural effusions, intraabdominal fluid collections can be percutaneously sampled or drained safely at the bedside under real-time ultrasound guidance (Fig. E2-27).

FIGURE E2-27 ■ Transverse view of a left lower quadrant abdominal collection. Echogenic, particulate material can be seen floating in the collection. Loops of bowel also are well visualized. A 6F catheter was inserted under ultrasound guidance to drain the collection, which was found to be chylous. Fluid collection with echogenic material and diffuse echoes on ultrasound are suggestive of particulate matter (e.g., fibrin or clots) and may represent an exudate or blood collection. (Courtesy Dr. Kurian Puthenpurayil.)

Urinary Bladder Scan

Bladder scanning devices are portable units that can provide a measurement of urine volume in the bladder (Fig. E2-28) and avoid bladder overdistention and reduce the need for unnecessary catheterization.^{191,192} Studies have shown that frequent catheterization is a major risk factor for urinary tract infections that can be costly to medical centers.¹⁹³⁻¹⁹⁵ Use of a portable bladder scanning device to reduce the incidence of nosocomial urinary tract infections was described by Moore and Edwards.¹⁹⁶ Bedside ultrasound assessment of volume in the urinary bladder also can be helpful to evaluate oliguria or anuria to rule out obstruction of the urinary catheter.

Focused Assessment of the Trauma Patient

Since the early 1990s, bedside ultrasound has been used in the United States as an additional diagnostic modality for use in determining the presence of intraabdominal injury after blunt trauma.¹⁹⁷ It is performed in the trauma bay during the secondary survey (as described in Advanced Trauma Life Support) or as part of the primary survey in hemodynamically unstable patients.^{191,198-202} The focused assessment for sonographic examination of trauma (FAST) should be done with a specific purpose, usually identification of hemoperitoneum, hemothorax, or tamponade.¹⁹¹ FAST seeks to determine the presence of fluid in four areas: (1) the subxiphoid region in the pericardial sac, (2) the right upper quadrant in Morison's pouch, (3) the left upper quadrant in the splenorenal recess, and (4) the pelvis in the pouch of Douglas or rectovesical space (Fig. E2-29).¹⁹ Because the FAST examination is non-invasive and quickly performed at the bedside, it is ideal for detecting intraabdominal injury in the resuscitation area. It has now been incorporated into the trauma resuscitation algorithm of most level I trauma centers in the United States.^{191,203}

Use of the FAST examination has been shown to diminish the need for more invasive diagnostic measures such as diagnostic peritoneal lavage and subsequent exploratory laparotomy.^{204,205} The FAST examination has been shown to be most accurate when performed for evaluation of hemodynamically unstable patients.^{203,206-208} Studies have suggested that its use as a screening tool for blunt abdominal injury in hemodynamically stable trauma patients may result in underdiagnosis of intraabdominal injuries.^{202,203,209}

FIGURE E2-28 ■ Urinary bladder. Suprapubic transverse view of a full urinary bladder (A). This “square” appearance of the bladder with a concave superior wall is typical of a moderately full bladder. When overdistended (i.e., in the presence of a low urinary tract obstruction), the bladder is large and adopts a round, globular shape (not shown). Suprapubic transverse view of an empty bladder (B). When empty, the bladder can become small and commonly may be difficult to identify. (Courtesy Dr. Kurian Puthenpurayil.)

FIGURE E2-29 ■ Focused assessment for sonographic examination of trauma (FAST). The FAST examination seeks to determine the presence of fluid in four areas: (1) the subxiphoid region in the pericardial sac, (2) the right upper quadrant in Morison's pouch, (3) the left upper quadrant in the splenorenal recess, and (4) the pelvis in the pouch of Douglas or rectovesical space.

Intraaortic Balloon Counterpulsation

Bedside TEE may be helpful in different aspects of intraaortic balloon counterpulsation management. Before insertion, TEE can rule out the presence of significant aortic regurgitation, which would represent a contraindication to intraaortic balloon counterpulsation use. After insertion, TEE can confirm the position of the intraaortic catheter in the descending thoracic aorta, ensure correct functioning of the balloon (visualization of inflation and deflation), and rule out the presence of important complications of aortic catheter insertion (e.g., aortic dissection). TEE also may be used for monitoring of the ventricular function while separating the patient from the intraaortic balloon counterpulsation device.

Ventricular Assist Devices

Different complications are likely to occur after ventricular assist device implantation, such as bleeding and hemodynamic instability. Maintenance of ventricular assist device flow is a key indicator of the overall status of the system. In the postoperative period, low ventricular assist device flow is usually due to hypovolemia and right ventricular dysfunction. TEE can be helpful for the diagnosis and monitoring of both of these conditions. Right ventricular failure has been shown to occur in approximately 20% to 25% of patients being supported with an isolated left ventricular assist device.²¹⁰ With prosthetic circulatory support devices, there can be dramatic changes in ventricular volumes and hemodynamic conditions and substantial direct and indirect changes to the contralateral ventricle due to ventricular interactions. TEE can help the clinician monitor and understand these ventricular interactions.²¹¹ It also can help assess adequacy of flow and the patency of the inflow and outflow cannulas to eliminate the presence of a thrombus and collapse or displacement of the cannulas. It also can motivate an urgent return to the operating room if a cardiac tamponade is diagnosed. If hypoxemia supervenes in the ICU, the presence of a patent foramen ovale has to be ruled out. For patients placed on extracorporeal membranous oxygenation support, bedside TEE also can be used to monitor ventricular function during weaning of the circulatory assistance.

Performance of Bedside Ultrasonography by the Intensivist

In acute situations in the ICU, it may be difficult to have a cardiologist or sonographer available on immediate call on a 24-hour basis to perform a bedside ultrasound examination. The value of immediate bedside echocardiography for aiding in diagnosis and management of acute hemodynamic disturbances has been well shown in the literature in the ICU and the emergency department.^{212,213}

Ultrasound technologies are not exclusive to the radiologist or cardiologist. Appropriately trained emergency department physicians, surgeons, anesthesiologists, and ICU specialists have been using ultrasound devices with great success. Anesthesiologists were instrumental in many of the pioneering studies of TEE in the operating room and ICU.^{4,22,214,215} Successful performance of bedside echocardiography by noncardiologist intensivists also has been well shown in the literature.^{8,21,216} A study by Benjamin et al.²¹ showed that a limited TEE examination performed and interpreted by intensivists (after training under the supervision of two cardiologists) is feasible and provides rapid, accurate diagnostic information that can have a dramatic impact on the treatment of critically ill patients.²¹ The safety and utility of performance of bedside ultrasound by the intensivist for various other purposes in the ICU (central venous cannulation, thoracentesis, paracentesis) also have been well shown.^{170-172,189}

With the increasing popularity of ultrasound devices—particularly lightweight, portable, handheld devices—there is controversy regarding the advisability and use of noncomprehensive “goal-directed” examinations performed by clinicians without cardiology or radiology training.¹⁰⁴ Studies with these portable devices that provide basic 2D and Doppler flow imaging showed they can provide important anatomic information²¹⁶⁻²²⁰ but that even in highly skilled hands, they may provide suboptimal imaging or diagnostic capabilities in the ICU.²¹⁸ Inappropriate interpretation or application of data gained by a poorly skilled user may result in adverse medical, ethical, and social consequences.¹⁰⁴ To avoid misusing the technology, adequate training is essential.

The era of a technology-extended physical examination²¹⁹ seems to have arrived, and there seems to be a role for a user-specific, focused ultrasound examination.^{104,221} An examination said to be “targeted,” “focused,” and “limited” may often equate with “incomplete,” “inadequate,” or “inaccurate.” Training must be individualized and tailored to specific needs, and appropriate user-specific application depends directly on the training and expertise of the user.¹⁰⁴ Provided that adequate expert backup is available, the training of intensivists in performing focused or more comprehensive bedside ultrasound examinations is not only feasible but also can be done safely and rapidly and yield information pertinent to the management of critically ill patients. General guidelines in training for TTE and TEE have been developed by the American Society of Echocardiography in association with the American Heart Association and the American College of Cardiology.²²² Since 1996, the American Society of Anesthesiologists and Society of Cardiovascular Anesthesiologists also have developed practice guidelines for perioperative TEE.²²³ The importance of adequate training and subsequent maintenance of competence cannot be overemphasized; inappropriate use or misapplication potentially could temper the acceptance and limit the value of performance of bedside ultrasonography by the intensivist.

Training of intensivists and emergency department physicians in performance of emergency bedside ultrasonography should provide rapid answers to clinical questions that may strongly affect medical and surgical management decisions. As has been mentioned by different authors,^{190,224} training in echocardiography and general ultrasonography should be incorporated into the critical care fellowship, with special emphasis on TEE as part of the training program. It is hoped that critical care and echocardiographic societies will credential such additional training in the near future.

KEY POINTS

1. As a result of improvements in transthoracic imaging, most ICU patients now can be adequately studied with transthoracic echocardiography (TTE).
2. Transesophageal echocardiography (TEE) is particularly useful in the ICU for the assessment of unexplained hypotension, suspected aortic dissection, valvular vegetations, source of cardiac or aortic emboli, prosthetic heart valves (especially mitral), and detection of intracardiac shunts.
3. The use of ultrasound guidance during central venous catheterization has been well shown to reduce the risk of complications, improve rapidity of catheter placement, and improve overall success of the procedure.
4. Successful performance of bedside ultrasonography by intensivists in a limited examination has been shown to be feasible and potentially to provide rapid diagnostic information that can have a dramatic impact on the treatment of critically ill patients.
5. Adequate training and maintenance of competence is crucial for the intensivist to perform bedside ultrasonography safely and efficiently, because inappropriate interpretation or application of data gained by a poorly skilled user may result in adverse consequences.

BEFORE PROCEDURE

Indications

- Cannot achieve the goal with peripheral intravenous catheterization
 - Rapid, massive intravascular volume resuscitation
 - Peripheral catheters are often difficult to place in shock states.
- Fast flow rate is required.
 - 3.5-inch, 8.5F introducer catheter has the fastest flow rate.
 - However, a 2-inch, 16-gauge peripheral catheter has a faster flow rate than a 16-gauge centrally inserted triple-lumen catheter
- Cardiopulmonary resuscitation
 - Drug administration is more effective centrally.
- Administration of agents irritating to peripheral veins
 - Concentrated potassium chloride solutions
 - Total parenteral nutrition solutions
 - Chemotherapy agents
 - Vasopressors and inotropes
- Central venous pressure monitoring
- Pulmonary artery pressure monitoring
- Transvenous pacemaker insertion
- Hemodialysis
- Plasmapheresis
- Venous access for frequent blood sampling

Contraindications

- No absolute contraindications if experienced or supervised operator
- Relative contraindications
 - Severe coagulopathy (including thrombocytopenia)
 - Consider a femoral vein central catheter or peripherally inserted central catheter (PICC).
 - Local skin infection
 - Ipsilateral arteriovenous fistula
 - Ipsilateral venous thrombosis
 - Inferior vena cava filter
 - Avoid passing the wire beyond 20 cm during central line insertion to prevent entanglement.

Equipment

- Catheter appropriate for the indication (e.g., single lumen, multilumen, 8.5F introducer)
- Insertion kit, including 10-mL syringes, needles, guidewire, suture material, and local anesthetic
- Sterile saline flush solution
- Sterile fenestrated barrier drape for head-to-toe coverage of the patient
- Four sterile towels
- 2% Chlorhexidine gluconate sterile prep stick
- Sterile gown and gloves for the operator and assistant(s)
- Cap and mask with a face shield or protective glasses for the operator and assistant(s)

- Sterile central line dressing kit
- Shoulder roll (for subclavian vein catheterization)
- Ultrasound (for internal jugular vein catheterization)
- Sterile sheath, gel, and needle guide for ultrasound

ANATOMY

The pertinent anatomy varies depending upon the chosen site of central venous catheterization. All relevant landmarks should be included in the sterile field. For internal jugular venous catheterization, identification of the triangle formed by the two heads of the ipsilateral sternocleidomastoid (SCM) muscle is imperative. It is also important to note the location of the angle of the mandible, the clavicle, and the sternal notch (located between the medial ends of the right and left clavicles). The carotid artery pulse should be located and protected during placement of the needle into the internal jugular vein. For subclavian vein catheterization, the middle portion of the clavicle, insertion point of the clavicular head of the ipsilateral SCM muscle, and sternal notch should be identified. Femoral vein catheterization requires identification of the junction of the middle and distal third of an imaginary line drawn from the pubic tubercle to the anterior superior iliac spine. The ipsilateral femoral arterial pulse should be located as well.

PROCEDURE

- Internal jugular vein (middle approach)
 - Obtain informed consent from the patient or surrogate decision maker.
 - Gather all necessary equipment.
 - Place the patient in the supine position.
 - Position the bed at a comfortable height, with 15 to 30 degrees Trendelenburg.
 - Rotate the patient's head away from the side of insertion.
 - Perform nonsterile ultrasound to confirm patency and depth of the internal jugular vein and the location of surrounding structures.
 - Open the equipment using sterile technique.
 - Wash hands and don a cap, face shield mask, sterile gown, and pair of gloves.
 - Use a 2% chlorhexidine prep stick to prepare the area bounded by the ear lobe, mandible, chin, neck, and sternal notch past the midline, 2 cm inferior to the clavicle, and 2 cm posterior to the sternal head of the SCM muscle.
 - Preparing a wide area is preferred to facilitate conversion to the ipsilateral subclavian approach if the internal jugular approach is unsuccessful.
 - Square off the sterile area with 4 sterile towels.
 - Place the head-to-toe fenestrated sterile drape.
 - Place the ultrasound probe in a sterile sheath with gel and position the correct needle guide on the probe.
 - Find these anatomic landmarks: apex of the triangle formed by two heads of the SCM muscle, sternal notch, clavicle, and carotid pulse.
 - Locate the internal jugular vein with the ultrasound probe, and confirm that the vessel collapses easily with compression and is nonpulsatile.

- Inject local anesthetic into the skin and surrounding region at the proposed insertion site.
- Ensure that all materials needed for catheter placement are in easy reach within the sterile field.
 - Flush all catheter lumens, and then place caps on all ports except the distal port.
- Place the access needle with attached syringe onto the needle guide of the ultrasound probe.
- Advance the needle into the internal jugular vein under direct vision using ultrasound, applying gentle aspiration pressure on the syringe during advancement.
- Confirm the presence of the needle within the vein lumen by ultrasound imaging and by aspiration of free-flowing, nonpulsatile, venous-colored blood.
- Remove the needle from the needle guide on the ultrasound probe.
- If ultrasound is unavailable, insert the needle at the apex of the SCM triangle and advance the needle toward the ipsilateral nipple at a 30- to 45-degree angle while continually applying gentle aspiration pressure on the syringe.
- Place the curved end of the guidewire through the syringe and/or needle into the vein. Never lose control of the distal end of the guidewire.
- Using ultrasound, confirm the presence of the guidewire in the internal jugular vein.
- Remove the syringe and needle over the guidewire.
- Using a scalpel, make a small nick in the skin at the wire insertion site.
- Place a dilator over the wire, and advance the dilator into the soft tissues to establish a tract.
- Remove the dilator, leaving the guidewire in place.
- Place a catheter (single lumen or multilumen) over the wire into the vein:
 - 16 cm for the right internal jugular
 - 19 cm for the left internal jugular
- Remove the guidewire and place a cap on the distal port.
- Aspirate blood via all catheter lumens, and then flush each lumen with sterile saline.
- Secure the catheter to the skin with suture material.
- Place a sterile dressing.
- Clean up and safely discard all sharp objects.
- Order a chest x-ray to check catheter position.
- Subclavian vein (infraclavicular approach)
 - See Video E3-1
 - Obtain informed consent from the patient or surrogate decision maker.
 - Gather all necessary equipment.
 - Place the patient in the supine position with the ipsilateral arm adducted.
 - Place a shoulder roll under the patient, positioned vertically between the scapulae.
 - Position the bed at a comfortable height, with 15 to 30 degrees Trendelenburg.
 - Rotate the patient's head away from the side of insertion.
 - Open the equipment using sterile technique.
 - Wash hands and don a cap, face shield mask, sterile gown, and pair of gloves.
 - Use a 2% chlorhexidine prep stick to prepare the area bounded by the ear lobe, mandible, chin, neck, and sternal notch past the midline, 2 cm inferior to the clavicle, and 2 cm posterior to the sternal head of the SCM muscle.
 - Preparing a wide area is preferred to facilitate conversion to the ipsilateral internal jugular approach if the subclavian approach is unsuccessful.
 - Square off the sterile area with 4 sterile towels.
 - Place the head-to-toe fenestrated sterile drape.
 - Find these anatomic landmarks: midportion of ipsilateral clavicle and sternal notch.
- Inject local anesthetic into the skin and surrounding region at the proposed insertion site.
- Ensure all materials needed for catheter placement are in easy reach within the sterile field.
 - Flush all catheter lumens and place caps on all ports except the distal port.
- Insert the needle with attached syringe into the skin 2 cm inferior to the midportion of the clavicle, directing the needle slightly cephalad toward the clavicle in the direction of the sternal notch.
- "Walk" down the clavicle with the needle until it advances just deep to the inferior surface of the clavicle.
- While applying gentle aspiration pressure on the syringe, continue to advance the needle in the direction of the sternal notch until aspiration of free-flowing, nonpulsatile, venous-colored blood occurs, signaling entry into the subclavian vein.
- Place the curved end of a guidewire through the syringe and/or needle into the vein. Never lose control of the distal end of the guidewire.
- Remove the syringe and needle over the guidewire.
- Using a scalpel, make a small nick in the skin at the wire insertion site.
- Place the dilator over the guidewire, and advance the dilator into the soft tissues to establish a tract.
- Remove the dilator, leaving the wire in place.
- Place a catheter (single lumen or multilumen) over the wire into the vein.
 - 18 cm for the right subclavian
 - 20 cm for the left subclavian
- Remove the wire and place a cap on the distal port.
- Aspirate blood via all catheter lumens, and then flush each lumen with sterile saline.
- Secure the catheter to the skin with suture material.
- Place a sterile dressing.
- Clean up and safely discard all sharp objects.
- Order a chest x-ray to check the catheter position.
- Femoral vein
 - Obtain informed consent from the patient or surrogate decision maker.
 - Gather all necessary equipment.
 - Place the patient in the supine position with the ipsilateral thigh in slight abduction.
 - Open the equipment using sterile technique.
 - Wash hands and don a cap, face shield mask, sterile gown, and pair of gloves.
 - Use a 2% chlorhexidine prep stick to prepare an area bounded by the lateral mid thigh, medial mid thigh, and pubis in the midline, and extending 2 cm superior to an imaginary line connecting the pubis and anterior superior iliac spine.
 - Square off the sterile area with 4 sterile towels.
 - Place the head-to-toe fenestrated sterile drape.
 - Find these anatomic landmarks: pubic tubercle, anterior superior iliac spine, and femoral artery pulse.
 - Inject local anesthetic into the skin and surrounding region at the proposed insertion site.
 - Ensure that all materials needed for catheter placement are in easy reach within the sterile field.
 - Flush all catheter lumens and place caps on all ports except the distal port.
 - While applying gentle aspiration pressure on the syringe, insert the needle at a 90-degree angle into the skin medial to the femoral artery pulse at the junction of the middle and medial third of an imaginary line drawn from the pubic tubercle to the anterior superior iliac spine.
 - Continue to advance the needle until aspiration of free-flowing, nonpulsatile, venous-colored blood occurs, signaling entry into the femoral vein.

- Place the curved end of the guidewire through the syringe and/or needle and into the vein. Never lose control of the distal end of the guidewire.
- Remove the syringe and needle over the guidewire.
- Using a scalpel, make a small nick in the skin at the wire insertion site.
- Place the dilator over the guidewire, and advance the dilator into the soft tissues to establish a tract.
- Remove the dilator, leaving the guidewire in place.
- Place the catheter (single lumen or multilumen) over the guidewire into the vein.
- Remove the wire and place a cap on the distal port.
- Aspirate blood via all lumens, and then flush each lumen with sterile saline.
- Secure the catheter to the skin with suture material.
- Place a sterile dressing.
- Clean up and safely discard all sharp objects.
- Catheter malposition
- Venous thrombosis
- More frequent with femoral vein catheters
- Catheter-related bloodstream infection
- Infrequent
 - Pneumothorax
 - Hemothorax
 - Chylothorax (thoracic duct injury)
 - More common with left internal jugular or subclavian vein catheterization
 - Local nerve injury
 - Entanglement with vena cava filter
 - Tracheal perforation
 - Endotracheal tube cuff rupture
- Serious, rare complications
 - Air embolus
 - Cardiac tamponade

AFTER PROCEDURE

Postprocedure Care

- Obtain a chest x-ray.
 - To confirm the location of the internal jugular and subclavian venous catheter tip at the atriocaval junction
 - To rule out the presence of a hemothorax, pneumothorax, or apical cap
- Inspect the catheter insertion site daily to detect the development of infection.
- Monitor for arrhythmias, as catheter migration may occur.
- Maintain proper local dressing care to minimize complications.
- Access all ports in a sterile manner at all times.

Complications

- Common
 - Cardiac arrhythmias
 - Arterial puncture
 - Hematoma

OUTCOMES AND EVIDENCE

- Femoral vein catheters have a higher incidence of infectious and thrombotic complications compared with subclavian vein catheters.
- Lowest infection rates are associated with subclavian vein catheters.
- Infection of central venous catheters is diminished by judicious attention to sterile insertion technique.
- Antibiotic-treated, noncuffed central venous catheters are associated with a lower rate of device-related bloodstream infection than nontreated catheters but a higher rate when compared to PICCs.
- Use of ultrasound to guide insertion is beneficial in reducing mechanical complications and improving rates of successful cannulation, particularly when accessing the internal jugular vein or when operators are inexperienced.
- PICCs may be more cost-effective and have lower complication rates than centrally inserted venous catheters.
- Deep venous thrombosis due to PICCs may be related to catheter size.

Arterial Cannulation and Invasive Blood Pressure Measurement

Phillip D. Levin and Yaacov Gozal

Peripheral artery cannulation is one of the most commonly performed invasive procedures in the intensive care unit (ICU),¹ and the resulting arterial line is an integral part of intensive care patient management. Arterial line usage varies according to unit type, patient age, and severity of illness, ranging from approximately 22% of medical ICU patients to over 50% of surgical ICU patients. There are three main indications for arterial line insertion: (1) to allow continuous beat-to-beat monitoring of blood pressure; (2) to provide pain-free, convenient, and repeated access to arterial blood for the assessment of pulmonary and cardiovascular function (including measures of pulse pressure variation and semi-invasive cardiac output measurements using transpulmonary thermodilution); and (3) to provide a source of blood for blood tests as required without the need for repeated venipuncture including continuous measures of blood chemistry (such as continuous glucose measurement). A review of the relevant anatomy, equipment, and techniques for arterial line placement is provided in this chapter along with some of the more common complications.

SITES OF INSERTION

An arterial line can be inserted into almost any palpable peripheral artery. The most common sites in clinical practice are the radial artery (employed in up to 78% of ICU patients^{2,3}), the femoral artery (employed in up to 45%^{2,3}), and the dorsalis pedis artery. Axillary and ulnar artery cannulations are performed somewhat more rarely; brachial and temporal artery cannulation is not recommended. Cannulation of the carotid arteries is absolutely contraindicated for obvious reasons. Each arterial site has advantages and disadvantages.

The Radial and Ulnar Arteries

The radial artery originates in the antecubital fossa at the level of the neck of the radius as a terminal branch of the brachial artery. The artery runs down the length of the forearm laterally. For the distal part of its course it is covered only by fascia and skin and lies above the radius, where it is easily palpated. At the level of the wrist the artery winds laterally around the radius and enters the posterior aspect of the hand. It terminates by dividing into the superficial and deep palmar arches, which are anastomosed with the ulnar artery. The radial artery lies near the superficial branch of the radial nerve in its distal course.

The ulnar artery is the other terminal branch of the brachial artery, also originating in the antecubital fossa at the level of the radial neck. It is usually larger than the radial artery. The ulnar artery runs medially along the length of the forearm. As opposed to the radial artery, for most of its course the ulnar artery lies deep to the muscles of the forearm, becoming superficial only toward the wrist. The ulnar artery lies close to the ulnar nerve in its distal course.

When compared with the ulnar artery, the radial artery is superficial for a longer part of its course, is easily palpated above the radius, and is less closely associated with neural structures. It is, however, a smaller artery. The radial artery is cannulated within a few centimeters of the anterior wrist creases, where it lies conveniently over the radius.

Advantages

Advantages of radial artery cannulation include huge experience and safety, peripheral position, double blood supply to the dependent

territory (by the ulnar artery), and easy compression in the event of bleeding.

Disadvantages

Disadvantages include technical difficulties owing to the small size of the vessel or vasoconstriction (the radial artery pulse may not be palpable when blood pressure is less than 80 mm Hg) and inaccurate blood pressure measurements (when compared with the central circulation).⁴⁻⁶

The modified Allen test has been proposed as a screening tool prior to radial artery cannulation to ensure the presence of adequate distal collateral circulation.^{7,8} The Allen test has, however, been found to have high interobserver variability⁹ and to lack sensitivity and specificity.^{10,11} It is not widely used. Radial artery catheterization for coronary angiography has been compared in patients with normal and abnormal Allen tests with no significant adverse events occurring in patients with an abnormal Allen test.¹² It might be prudent, however, to avoid insertion of an arterial catheter into the radial or ulnar artery when the other artery is known to be absent or occluded.

Positioning for Cannulation

The forearm should be supine and the wrist slightly extended and supported (Video E4-1).

The Axillary and Brachial Arteries

The axillary artery is a continuation of the subclavian artery, beginning at the outer border of the first rib. The artery is surrounded by the cords of the brachial plexus. Its position relative to the other structures of the axilla varies according to the position of the arm. The artery ends at the inferior border of the teres major muscle, where it becomes the brachial artery. The brachial artery runs down the upper arm to the elbow. Initially, it is medial to the humerus, but distally it spirals anteriorly to end as the radial and ulnar arteries approximately 1 cm distal to the elbow. The brachial artery lies near the ulnar and median nerves in its proximal course and near the median nerve in its distal course.

Advantages

The axillary artery is a large artery, and pressure measurements reflect the central circulation.

Disadvantages

The arm position required for axillary artery cannulation may be contraindicated or difficult for some patients. Care should be taken if a long catheter is used, because its tip might be proximal to the origin of the brachiocephalic artery/left common carotid artery. In this case embolic material from the line (i.e., air bubbles or thrombus) could be introduced into the brain. The risk of line infection may also be higher relative to other sites.¹³

Positioning for Cannulation

For axillary artery cannulation the arm should be bent at the elbow and raised above the head (abducted and flexed to 90 degrees). The pulse can then be palpated in the axilla.

The brachial artery is punctured where it is palpable medially on the anterior aspect of the elbow. Generally, cannulation of the brachial

artery is not recommended, because it is associated with specific and potentially severe complications (see later). Despite this, large case series with low complications rates have been published.¹⁴

The Femoral Artery

The femoral artery originates as a continuation of the external iliac artery at the level of the inguinal ligament. At the level of the inguinal ligament, it lies midway between the anterior superior iliac spine and the symphysis pubis. Distal to the inguinal ligament, the artery lies medial to the femoral nerve and lateral to the femoral vein and is superficial, being covered only by fascia, fat, and skin. The femoral artery runs down the thigh and terminates as the popliteal artery in the knee.

Advantages

The femoral artery is a large artery that is easier to locate and puncture than the radial artery. Blood pressure measurements reflect central blood pressure, and the femoral artery is palpable at a lower blood pressure than the radial artery. The femoral arterial line has a lower rate of catheter malfunction and greater longevity (compared with the radial artery).³

Disadvantages

In obese subjects, adipose tissue and skin folds may create difficulties in the approach to the groin. The skin over the puncture site also can be compromised by chronic inflammatory changes or fungal infections, and the artery itself may be very deep and difficult to locate. The insertion site also may be difficult to keep clean and well dressed. The risk of hemorrhage into the retroperitoneal space (which may initially be undetectable clinically) is unique to this site. Hemorrhage (either retroperitoneal or percutaneous) is also a risk when removing femoral artery catheters, particularly in patients with deranged clotting. The femoral artery is a common site for vascular surgery in the leg, and this represents a strong relative contraindication to arterial cannulation.

Position for Cannulation

In a supine patient, assistance may be required in retracting abdominal and thigh adipose tissue to allow access to the groin.

Dorsalis Pedis

The dorsalis pedis artery begins anterior to the ankle as a branch of the anterior tibial artery. The artery runs distally in the foot between the tendons of the extensor digitorum longus and extensor hallucis longus. It terminates as it turns in to the foot toward the sole between the first two metatarsal bones. During its course over the foot the artery is covered only by fascia and skin and is easily palpable.

Advantages

The dorsalis pedis is an easily accessible, compressible small artery.

Disadvantages

This artery is the most distant from the central circulation. Vasoconstriction can affect the quality of the arterial signal. In addition, the distance from the central circulation may result in an artificially elevated systolic pressure reading that is caused by interaction of the arterial pressure wave on smaller and smaller arteries.¹⁵

Position for Cannulation

The foot is placed in a neutral position with slight extension of the ankle.

Additional Considerations

From this discussion of relative anatomy the features of the arteries commonly used for monitoring become clear: all are superficial,

covered only by fascia and skin, easily palpable, and easily compressible. The specific artery chosen for insertion of an arterial line should be influenced by the experience of the operator, ease of palpation, contraindications, and limitations in positioning.

After adequate positioning, the chosen arterial line insertion site should be cleaned and sterilized with a solution containing >0.5% chlorhexidine in 70% alcohol. For femoral or axillary artery insertion maximum sterile barrier precautions should be used—cap, mask, sterile gown, sterile gloves, and full body sterile drapes. For insertion of peripheral artery cannulas, the operator should at the minimum don a cap, mask, and sterile gloves and use a small sterile fenestrated drape at the insertion site.¹⁶ Local anesthesia (approximately 1 mL of 1% to 2% lidocaine *without epinephrine*) should be infiltrated around the insertion site using a small-gauge (24- to 26-gauge) needle. Epinephrine should be avoided as an additive to the local anesthetic in order to prevent arterial spasm.

EQUIPMENT

Before actually inserting the arterial cannula, the monitoring equipment, cables, arterial line setup, and adhesive tape/sutures should all be prepared and checked. Beyond the arterial cannula, the arterial line setup consists of noncompliant tubing; three-way taps (stopcocks), a pressure-transducing device, a flush system, and the monitor. The arterial cannula is connected to a short length of tubing and then to at least one three-way tap. This tap is used for blood sampling and may also be used for zeroing the setup. The three-way tap is, in turn, connected to the pressure-transducing device, which is connected to the monitor. The pressure transducer is also connected to the flush system. The flush system consists of a bag of intravenous fluid under pressure from which all air has been removed. The fluid bag is compressed to a pressure greater than the arterial pressure using a pressure bag or cuff. The flush system maintains a continuous but slow (3 mL/h) flow of fluid through the system and into the artery to maintain cannula patency. The arterial line system may include additional three-way taps, connections to other pressure monitoring sites (e.g., central venous pressure), and damping devices as required.

Sets for Arterial Cannulation and Insertion Technique

A multiplicity of arterial cannulation sets exists, falling into three main groups: sets based on a cannula-sheathed needle (equivalent to the normal intravenous catheter) with or without an additional wire, sets based on the Seldinger technique, and sets used for direct arterial cutdown techniques.

The simplest technique for arterial line insertion employs a 20-gauge catheter-over-needle arrangement. A simple 20-gauge intravenous cannula can be used, although catheters specifically made for arterial puncture are available. Such a catheter is suitable for the smaller arteries (radial or dorsalis pedis). After appropriate positioning, the patient's pulse is palpated with the nondominant hand and the cannula inserted at an angle of 45 to 60 degrees to the skin and into the artery using the dominant hand. The cannula and needle may be advanced until blood flashback is seen in the needle, and then the cannula is threaded into the artery (in a manner similar to intravenous insertion). Alternatively a through-and-through technique can be employed. In this technique, the needle and cannula are inserted directly through both the front and back walls of the artery without seeking blood flashback. The needle is withdrawn partially or fully from the cannula. The cannula is then slowly drawn back until the blood flashback is seen and subsequently threaded into the artery. In the event that blood flashback is not seen, the needle should not be reinserted into the cannula because it may perforate the side or cut off a distal segment.

Occasionally, difficulty may be found in inserting the cannula despite good backflow of blood through it. In this circumstance, the arterial line wire may be of use. The wire fits through the cannula (after the needle has been removed) and may be manipulated into the artery.

The wire need only be inserted a few centimeters beyond the catheter tip (into the artery), and the cannula can then be threaded. As a precondition to wire insertion, good back-flow of blood must be noted through the cannula, and under no circumstances should the wire be inserted with force, because this can lead to perforation or dissection of the artery.

Some cannula-over-needle sets include a wire that is preconnected to the needle/cannula apparatus. These sets are available for both smaller and larger arteries and represent a combination of the guidewire and Seldinger techniques. The artery is punctured by one of the techniques described earlier using the needle and cannula assembly. Blood flashback is seen in the tube housing the wire. Once blood is seen to return, the wire is advanced through the needle while it is still (at least partially) within the cannula and into the artery. The cannula is then advanced over the wire into the artery.

For larger or deeper arteries (femoral and axillary), sets based on the Seldinger technique are available. Using this technique, the artery is punctured with a needle, the wire is inserted through the needle, the needle is removed, and the catheter is inserted over the wire. This differs from the wire technique described earlier, because the wire is inserted through the needle, and then the needle is removed before the cannula is inserted.

Arterial cannulation can be very challenging, especially in patients with severe peripheral vascular disease or low blood pressure. Under these circumstances, additional equipment may be required to help locate the artery. Both Doppler and ultrasound probes may be useful.

The Doppler probe provides an auditory signal corresponding to blood flow. The characteristic arterial pulse form is easily distinguished from venous blood flow. The point of maximal Doppler response lies directly above the artery and may help in directing the needle to localize the artery.¹⁷

By using ultrasound with a high-frequency probe the artery may be visualized. On short axis it is seen as a pulsating echogenic (white) ring on cross section. The arterial catheter needle can also be seen on ultrasound (as a straight echogenic line) and can thus be directed into the artery. Needle insertion can be performed either out of plane using the short-axis image or in-plane using the long-axis view. Two recent meta-analyses demonstrated that use of ultrasound increases the chances of first-time success and decreases the time required for insertion.^{18,19}

Cutdown techniques are rarely required in adults. This issue for pediatric patients is addressed in Chapter 228.

Once inserted, the arterial cannula should be well fixed to the patient to prevent accidental removal and connected to the flush/pressure transduction system. Consideration can be given to using a sterile semipermeable dressing to cover the insertion site with the addition of adhesive tape. Once the presence of an adequate waveform on the monitor has been confirmed, the next step is to zero the system.

Zeroing

The importance of accurate zeroing cannot be overstated—zeroing problems reflect one of the most common sources of error in pressure-transduction systems. Zeroing has two main functions: the first is to equilibrate the monitor, and the second is to correct for the contribution of the fluid column in the pressure-transduction system between the patient and the pressure transducer.

The pressure transducers in use today are rugged, inexpensive, and accurate.²⁰ They convert pressure applied from the artery via the fluid-filled tubing to the transducer into electrical energy. The electrical signal generated by the transducer is then amplified in the monitor to produce a waveform on the screen and a numeric measure of blood pressure. The conversion of mechanical pressure into an electrical signal requires an “excitation voltage” to be provided by the monitor to the transducer. The standard responsiveness of the transducer is 5- μ V/V excitation voltage/mm Hg,²⁰ and atypical excitation voltage is 6 V. Therefore, the pressure transducer produces 30- μ V/mm Hg pressure applied from the artery. Typically, this signal is amplified 1000

times by the monitor, so that for each 100 mm Hg of blood pressure the monitor output is 3 V.²⁰ Before their first use, and periodically during their use, the interaction of the excitation current, the transducer response, and the monitor amplification requires resetting—in the first instance to standardize the system and thereafter to compensate for any drift. This calibration is achieved by zeroing or standardizing the measurement to atmospheric pressure, which thereafter is the zero reference point for further measurement. With current semiconductor equipment, calibration to a mercury manometer is not required.²⁰

The arterial line is zeroed by exposing the pressure transducer to atmospheric pressure, for example, by turning one of the three-way taps such that it is closed to the patient and the transducer is open to room air. The zero procedure is activated on the monitor and the system left untouched for a few seconds until a flat line appears on the arterial monitor tracing and the monitor reads zero. The three-way tap is then closed to air and opened to the patient, and blood pressure can be measured. The zero point (the three-way tap used for zeroing) can be near to the patient or near to the transducer. It is important to consider that the pressure measured by the monitor will represent the patient's arterial pressure plus any contribution made by the column of fluid in the pressure tubing between the patient and the zero point.

To illustrate this point, consider the change in pressure reading if the pressure transducer is lowered by 100 cm to the floor. In addition to the patient's blood pressure acting on the pressure transducer, a column of water 100 cm long is also present and contributes to the pressure reading. The blood pressure reading is in millimeters of mercury, so it will increase by 100/1.36, or by 73 mm Hg. If the pressure transducer is raised relative to the patient, then the pressure recorded by the monitor will decrease in a similar manner. Appropriate zeroing of the pressure transducer can compensate for these differences. Continuing the example above, while the transducer is 100 cm lower than the patient, the three-way tap near the patient's radial artery is closed to the artery and opened to room air. The monitor is rezeroed. Now the zero incorporates the contribution made by the 100-cm column of water in the tubing, and when the arterial pressure is measured again, it will once more be accurate. Although this example is extreme, smaller changes in relative position are common; the transducer is attached to the patient at the level of his shoulder while he is supine. The patient is subsequently repositioned from supine to sitting. His shoulder is raised by 20 cm relative to his femoral artery, and the pressure recorded on the monitor decreases by $20/1.36 = 15$ mm Hg. This change might not cause a change of therapy if arterial pressure is being measured. However, if intracranial pressure (ICP) is being measured, for example, a 15-mm Hg inaccuracy in the measurement could be critical. By convention, for arterial pressure measurement, the zero point is set at the height of the right atrium (i.e., the midaxillary line in the supine patient).

Damping

Another potential source of error in the measurement of blood pressure using the arterial line results from the interaction between the arterial pressure wave and the physical properties of the arterial line setup. This interaction can lead to underdamping (resonance or overshoot) and a spuriously high blood pressure reading or overdamping with a spuriously low blood pressure.

The arterial pulse waveform can be described as a summation of component sine waves with frequencies that are mainly in the range of 3 to 5 Hz. The arterial line set tubing has a natural frequency that is usually greater than 20 Hz. If the natural frequency of the arterial line set is decreased, it can approach the component frequencies of the arterial pulse waveform, and resonance may occur or increase, resulting in underdamping. Resonance/underdamping modulates the pressures measured. The main effect will be an increase in the recorded systolic blood pressure. A decrease in the recorded diastolic blood pressure may also occur while, typically, mean blood pressure will not be affected. Perhaps the most common cause of underdamping is the

use of an excessive length of pressure tubing between the arterial insertion site and the pressure transducer. Underdamping also may be a problem when measuring central arterial pressures and in the presence of severe vasoconstriction.

Overdamping decreases the transfer of energy from the artery to the pressure transducer. Overdamping results from the absorbance of energy by the fluid contents of the arterial set tubing and the tubing wall itself and from the friction between them. Damping is quantified by the damping coefficient (zeta), a measure of the time required for the system to come to rest after activation. Increased damping decreases the recorded systolic pressure and, to a lesser extent, increases the recorded diastolic pressure; mean pressure is affected the least. Damping is increased by the use of compliant, kinked, or partially occluded tubing and by loose connections and leaks (Box E4-1).

To obtain an accurate measure of the blood pressure from the arterial line, the system must be properly balanced. One method to assess balance utilizes the “fast flush test.”^{21,22} This test is performed by activating the flush device for a few seconds and then releasing it. On activation of the flush device, the pressure measured rises to a plateau. After release, the pressure waveform drops abruptly and small sharp waves may be seen (Fig. E4-1). In a balanced system, there should be only one such sharp wave. Figure E4-1, A, shows a system that is underdamped; there are multiple sharp waves after release of the flush. The reason for the underdamping in this case was the use of an

excessive length of pressure tubing. Figure E4-1, B, shows the effect of removing the excess length of pressure tubing. Only one sharp wave follows the flush, indicating that the system is now well balanced. An alternative correction that could have been applied (if the tubing length was required) might have been to increase the damping coefficient with the aid of a dampening device. Using this device is similar in effect to introducing a small air bubble in to the arterial line tubing; however, its use does not incur the risk of air embolus.

Figures for the natural frequency and damping coefficient of an arterial line setup can be approximated from a tracing of the fast flush test.²² The natural frequency of the arterial line setup can be calculated from the cycle length of the sharp waves, whereas the damping coefficient can be calculated from the rate at which the waves decline in amplitude. Figure E4-2 shows an enlargement of the flush release in the underdamped arterial line tracing in Figure E4-1, A, and illustrates the calculation. Based on this tracing, the natural frequency was calculated at 22.7 Hz, while the damping coefficient was 0.34. Removal of the excess tubing (producing the tracing in Fig. E4-1, B) resulted in a natural frequency of 50 Hz, while the damping coefficient was unchanged.

Flush Solutions

To maintain patency and prevent thrombosis of the arterial catheter, it must be continually flushed. Numerous additives have been proposed to achieve this aim, including heparin (the most commonly used), sodium citrate, papaverine, and normal saline. The infusion of heparin through the arterial catheter has been shown to be more effective than normal saline in maintaining patency and/or arterial pressure measurements. However, a recent Cochrane review revealed clinical and statistical heterogeneity in the seven studies and 606 patients included and prevented the definitive demonstration of an advantage to heparin over normal saline.²³ When used, the concentration of heparin in the arterial line flush is usually less than 10 units/mL, with 1 unit/mL being common. Concentrations as low as 0.25 unit/mL, infused at 3 mL/h, are efficacious.²⁴

Sodium citrate (1.4% solution) has been suggested as a flush solution that avoids the potential complications associated with the use of heparin and has been found to be equally effective.²⁵ Papaverine is an additional alternative.^{26,27} Dextrose-containing solutions are not recommended for flushing the arterial line.¹⁶

The use of flush solutions, although beneficial, is associated with potential complications, mainly in their effect on blood test samples obtained through the arterial line as described below. However, infusion of the wrong flush solution—including potassium-containing solutions, x-ray contrast, antibiotics, and others—can also lead to complications.²⁸ Using the wrong solution has been reported in 30% of ICUs.²⁹

COMPLICATIONS

The cumulative experience with arterial lines in patients in ICUs is huge; therefore, there is a considerable body of literature concerning complications. Overall, major complications are rare—15/17,840 (0.084%) in one study.³⁰ Complications are associated with the introduction and maintenance of a cannula in the artery and with its use. Common complications have been collected into series, whereas individual case reports describe a wide spectrum of rarer occurrences. The more common complications are described.

Vascular and Local Complications

Vascular and local complications vary from the clinically mild (small hematoma formation, insignificant bleeding) to catastrophic (permanent ischemic limb damage). A summary of 78 studies concerning the incidence rates for vascular and local complications of radial, femoral, and axillary arterial lines has been published and is summarized in Table E4-1.³¹ Temporary arterial occlusion is common for all sites; the

BOX E4-1

Causes of Underdamping (Overshoot) and Overdamping

CAUSES OF UNDERDAMPING

Central pressure measurement
Long pressure tubing
Marked vasoconstriction

CAUSES OF OVERDAMPING

Air in tubing
Blood clots
Compliant tubing (not stiff-walled pressure tubing)
Kinked arterial catheter
Leaks in system (hole in tubing)
Loose connections

FIGURE E4-1 ■ The fast flush test, electrocardiogram, and arterial line tracings. Tracing A shows underdamping or overshoot with multiple sharp waves following the release of the flush device (speckled arrow). Tracing B shows a balanced system, with only one sharp wave following flush release. The white arrowheads indicate the beginning of the system flush, whereas the black arrowheads represent its termination.

$$\text{Natural frequency} = \frac{\text{Paper Speed (mm/sec)}}{\text{Cycle Length (mm)}} = \frac{25}{1.1} = 22.7 \text{ Hz} \quad (\text{Equation 1})$$

$$\text{Damping Coefficient} = \frac{\left(\ln \frac{D2}{D1} \right)^2}{\pi^2 + \left(\ln \frac{D2}{D1} \right)^2} \quad (\text{Equation 2})$$

A

Inserting values from the figure above:
 $D2 = 2.5 \text{ mm}$ $D1 = 7.8 \text{ mm}$ $D2/D1 = 0.32$,
 And from the graph below, or the calculation, Damping coefficient = 0.34

Graphical representation of (Equation 2) – the relation between $D2/D1$ and the damping coefficient

smaller radial artery is at greater risk than the larger femoral and axillary arteries. Arterial occlusion occurs in part as a result of mechanical obstruction of the artery by the cannula and in part by the formation and propagation of thrombus. Despite its high incidence, arterial occlusion is not detrimental in the majority of cases.^{10,31,32} The arteries recannulize rapidly (within a week),^{8,10,32-34} and permanent ischemic sequelae of arterial cannulation are, fortunately, rare.^{31,32} Attempts have been made to correlate a wide variety of factors with increased risk of arterial obstruction, and some of these are summarized in **Box E4-2**. The use of Teflon catheters has been associated with a decreased risk of arterial thrombosis,^{33,35,36} whereas outcome is independent of the age of the patient.^{37,38}

BOX E4-2

Factors Associated with Increased Risk of Arterial Obstruction

Use of smaller arteries (radial and dorsalis pedis vs. femoral or axillary³¹)
 Large catheter size^{33,102}
 Multiple insertion attempts^{33,37}
 Presence of hematoma¹⁰
 Female sex^{10,33,38}
 Preexisting peripheral vascular disease³²
 Prolonged shock³²
 Use of vasoconstrictor drugs³²

Catheterization of the brachial artery is generally not recommended because of potentially severe complications. These include forearm ischemia (secondary to mechanical obstruction of the artery by the catheter and/or thrombus), compartment syndrome (described in case reports³⁹⁻⁴¹), and damage to the median nerve (from either ischemia, direct mechanical trauma, or pressure secondary to a hematoma⁴²). Anticoagulation has been associated with a number of these complications^{39,43,44} and represents a relative contraindication.

Despite the widespread recommendation not to cannulate the brachial artery, its use has been reported in 3% of ICU patients² and up to 20% of operating room patients.¹⁴ Wider experience has been described in other specialties (e.g., angiography, single puncture for blood gases,⁴⁵ and long-term access to the arterial circulation) and provides an indication of potential complication rates. In a study of 10,500 patients undergoing cardiac angiography via the brachial artery, surgical intervention was required for 0.57%, most commonly due to hand ischemia.⁴⁶ The incidence of median nerve damage after cardiac catheterization via the brachial artery is 0.2% to 1.4%,⁴² whereas vascular angiography performed through the brachial artery in 1326 patients was associated with a brachial artery thrombosis rate of 0.28% for men and 1.24% for women.⁴⁷ Long-term cannulation of the brachial artery has been described in a study of 225 transbrachial intrahepatic cannulas (in situ for up to 14 months) and was associated with diminished radial pulses in 88 (39%) patients and ischemic symptoms of the forearm in 16 patients (8%). Brachial artery thrombosis had an incidence of 1.7%.⁴⁸

In clinical practice, the territory supplied by an artery that has been cannulated should be closely monitored. Pain, weakness, changes in sensation, pallor, or decreased temperature all suggest compromised arterial blood flow and should prompt the immediate removal of the arterial cannula. Usually removing the catheter will be sufficient to restore adequate blood flow.

Erroneous Blood Test Results

In 2008 the United Kingdom National Patient Safety Agency reported on two deaths related to erroneous results from blood tests obtained from the arterial catheter. In one of these, the arterial flush solution was changed from 0.9% sodium chloride solution to 5% glucose [*sic*]. Arterial blood glucose evaluations increased, and in parallel the insulin dose increased. After the patient lost consciousness blood was sent to the laboratory, and a glucose concentration of 0.1 mmol/L was detected. The patient never regained consciousness.²⁸ A second similar case report was published in 2013.⁴⁹

As reflected in these cases the most common cause of an unreliable blood test result is either dilution or contamination of the sampled blood with flush fluid. In addition to glucose measurements, removal of inadequate “dead-space” from the arterial line setup before obtaining blood for hemoglobin estimation may lead to a diluted sample and a falsely low hemoglobin level, and if heparin from the flush solution is introduced into a test of the activated partial thromboplastin time (aPTT), this test will be markedly prolonged. Heparin in higher concentration may also artifactually decrease the pH and PCO₂ measurements.^{50,51} If sodium citrate is used in the flush solution and inadvertently introduced into blood samples, then spurious hypocalcemia and a low pH might be reported along with increased glucose.⁵²

The solution to the problem of flush contamination lies in the withdrawal of an adequate deadspace of flush solution and diluted blood before obtaining the blood for testing. The interaction between heparin in the flush solution and the measurement of aPTT is particularly problematic and has been repeatedly studied in an attempt to determine the minimum deadspace volume required to obtain a reliable test result.^{53,54} Five to six times the tubing volume from the artery to the sampling three-way tap (i.e., the deadspace volume) should be withdrawn before the blood for this test to obtain a reliable result.

Whether this deadspace volume should be discarded or returned to the patient depends mainly on maintenance of sterility and speed of

sampling. Sterility can be maintained using a closed system, such that the deadspace blood is maintained in an internal reservoir. Specially designed systems exist with internal reservoirs^{55,56}; however, a simpler double-tap arrangement has also been described.⁵⁷ In this system, an extra three-way tap is added distal (i.e., farther away from the patient) to the sampling port. A syringe is attached to the extra three-way tap. The deadspace blood is drawn into this syringe, and the blood sample is taken from the more proximal (i.e., closer to the patient) tap. After blood sampling, the deadspace blood can be returned.

Blood cultures obtained from the arterial line represent another test in which results might be compromised. The sensitivity of cultures drawn in this way is similar to or slightly higher than that of blood cultures obtained by venipuncture; specificity, however, is lower.^{58,59} The lower specificity presumably reflects introduction of organisms into the culture bottles from the three-way tap or the catheter itself.

Anemia

The ease with which blood specimens can be obtained from the arterial line, and the requirement for frequent testing in critically ill patients, may lead to the removal of considerable volumes of blood. The effect of an arterial line in increasing blood test use was first reported in 1986.⁶⁰ In this study, patients with an arterial line in the ICU had blood drawn 3.4 times per day, leading to blood loss of 41.5 mL per day and a total of 762 mL. This was in contrast to non-ICU patients without an arterial line who had blood drawn 1.1 times per day, 12.4 mL/day, and a total of 175 mL for their whole admission.⁶⁰ Despite efforts to reduce iatrogenic blood loss, similar findings were published in 2015.⁶¹ Among 1894 cardiac surgery patients, the median phlebotomy volume remained high at 332 mL (vs. 118 mL for ward patients).⁶¹ Phlebotomy contributes to the development of anemia among ICU patients and has been implicated as a cause for blood transfusions.^{60,62} Relatively simple steps can reduce the blood loss associated with tests. Such steps include return of deadspace blood (as described earlier),^{55,57} use of pediatric-sized sample tubes,^{63,64} communication with the various laboratories to define the minimal blood volume required for various tests,⁶⁵ and point-of-care testing.⁶⁶ Despite their simplicity, these steps are infrequently employed.⁶⁷

Heparin-Induced Thrombocytopenia

The use of heparin can be associated with a syndrome of thrombocytopenia and thrombotic events usually appearing after approximately 5 days of heparin therapy.⁶⁸ HIT is thought to be mediated by IgG antibodies that develop in response to immunization against the heparin/platelet factor 4 (PF4) complex; these are called HIT antibodies.⁶⁸ The attachment of these antibodies to the heparin/PF4 complex on the platelet surface activates the platelets and induces thrombosis. Both venous and arterial thrombi can occur.⁶⁹ The presence of HIT antibodies does not, however, inevitably lead to thrombotic episodes. For example, up to 50% of cardiac surgery patients develop HIT antibodies, but thrombotic events are relatively rare (2%-3%).⁷⁰⁻⁷² The diagnosis of the HIT syndrome is therefore based on the presence of the antibodies, thrombocytopenia, and thrombotic events.⁶⁸

The overall incidence of this syndrome is reported to be approximately 5%. It is more common in women than men⁶⁸ and in surgical⁷³ as compared with medical^{69,74} or obstetric patients⁷⁵ and is also more common after the use of unfractionated heparin than low-molecular-weight heparin.⁶⁸ A single dose of heparin is sufficient to induce HIT,⁷⁶ and the presence of as little heparin as that found bound to heparin-coated central venous catheters may be sufficient to sustain the immune response.⁷⁷ The development of HIT antibodies has been linked with the administration of heparin in intravascular device flushes⁷⁸⁻⁸⁰ and also with low doses of heparin used in arterial flush solutions.⁸¹

Treatment for the HIT syndrome includes the cessation of administration of all sources of heparin, including those in the line flush solutions. The use of other anticoagulants for thrombotic episodes is recommended. Removing heparin from flush solutions also may be

indicated in the presence of HIT antibodies and thrombocytopenia before any thrombotic events.⁶⁸

After the decline in HIT antibody levels, the short-term use of heparin for certain indications (e.g., cardiac surgery) is considered acceptable.⁶⁸ It is prudent, however, to avoid heparin in the arterial line for patients with a history of HIT until further evidence of the risk of repeated episodes of HIT becomes available.

Infection

A patient may develop a bloodstream infection from the arterial line by one of three main routes. Infections have been introduced via infected equipment, such as reusable transducer domes⁸² or infected flush solutions⁸³; however, with the advent of disposable equipment and improved flush systems, the significance of this route of infection has declined. Two potential routes of infection remain: from the skin puncture site along the catheter and through the three-way taps.^{16,84-88} The predominant organisms associated with arterial line infection are gram-positive cocci (*Staphylococcus aureus* and *S. epidermidis*), although gram-negative rods may also be found.^{34,89,90}

Defining a precise rate of infection for the arterial line is not straightforward, because a multiplicity of definitions of catheter-related bloodstream infections is used in different studies and variables have not been standardized among studies. Clinical, research, and surveillance criteria exist for defining catheter-related infection. Clinical criteria include presence of signs of infection (e.g., fever, increased white blood cell count) associated with an arterial line in place longer than 96 hours with signs of local infection and no other source of sepsis. Whereas these criteria might be useful in clinical practice, they are too broad for research purposes. Surveillance criteria, such as those defined by the Centers for Disease Control and Prevention, include any significant bloodstream infection in the presence of a vascular catheter and no other source of sepsis.¹⁶ This definition overestimates the incidence of catheter-induced bloodstream infection because it includes bloodstream infection from occult sources other than intravascular lines.¹⁶ Research criteria can include the use of arterial line tip cultures (often quantitative or semiquantitative⁹¹) usually correlated to venous blood culture results.^{13,92,93} Combinations of these definitions have been employed.^{34,94}

With regard to arterial line variables, virtually every aspect of line insertion and maintenance (for either central venous or arterial catheters) has been examined for an effect on infection rate. Factors that have been evaluated include type of skin preparation solution used,⁹⁴⁻⁹⁶ insertion site, dressing type and care,^{16,87,88,97,98} arterial catheter length, site of insertion, catheter material, type of flush solution, and frequency of set changes (Box E4-3). Consistency is not found in the results of all these studies, and not all these factors have been standardized from study to study, possibly confounding direct comparisons.

Despite this variability, a meta-analysis reported that the rate of bloodstream infections related to arterial lines was 1.7 infections/1000 catheter-days and that 1.5/100 arterial catheters was found to cause a bloodstream infection.⁹⁹ These rates compared to 2.7 infections/1000 catheter-days and 3.6 infections/100 catheters for unmedicated central venous catheters (CVCs), 0.2 and 0.2 for antiseptic-coated CVCs, and

BOX E4-3

Factors Potentially Associated with a Change in the Infectious Risk of the Arterial Line¹⁶

INCREASED RISK

Cutdown technique versus percutaneous insertion⁹²
Duration of cannulation >96 h^{13,89,92,93,103}
Axillary artery site¹³
Frequent arterial line set changes¹⁰⁴

DECREASED RISK

Teflon catheters (vs. polyvinyl chloride)¹⁰⁵
Heparin (in central venous pressure and pulmonary artery catheters)¹⁰⁶
Use of chlorhexidine-containing skin preparation solutions^{94,95}
Factors not associated with a change in infectious risk
Femoral versus radial artery insertion site^{37,89}
Dorsalis pedis versus radial artery insertion site³⁴
Duration of catheterization >96 h^{37,90}
Systemic antibiotic prophylaxis before insertion⁹²

2.5 and 4.3 for antibiotic-coated CVCs.⁹⁹ The implication is that the infection rate associated with arterial catheterization is higher than generally assumed and may be higher than for the newer types of CVCs.

The Centers for Disease Control and Prevention summarized these diverse findings into these recommendations: use the radial, brachial, or dorsalis pedis sites rather than femoral or axillary arteries; use a minimum of cap, mask, sterile gloves, and a small sterile fenestrated drape for peripheral artery insertion and full sterile barrier precautions for axillary and femoral sites; use >0.5% chlorhexidine in 70% alcohol for skin preparation; do not change arterial catheters routinely; change the pressure monitoring sets and transducers every 96 hours; do not use dextrose in the flush solution.¹⁶ Despite these recommendations, and particularly the requirement for sterile precautions, less than half of physicians replying to a web-based survey adhered to them, indicating a need for education surrounding arterial catheter insertion.¹⁰⁰

In clinical practice, it is unlikely that an arterial cannula present for less than 96 hours is the cause of an infection. If the arterial line has been present for more than 96 hours, and no other source of sepsis is identified, strong consideration should be given to removing or replacing the arterial catheter. The presence of redness or pus at the arterial cannula introduction site should further increase the index of suspicion of an arterial line-related infection.

Finally, in view of these potential complications, the benefit of arterial cannulae in the ICU has begun to be questioned. Needless to say, there are no randomized controlled studies showing mortality benefit or harm from arterial cannulation. A recent retrospective study in a well-defined but limited population of hemodynamically stable patients with respiratory failure showed no difference in 28-day mortality.¹⁰¹ This study has led to calls to reassess the necessity for arterial cannulation in the ICU population in a similar manner to the assessments performed on pulmonary artery catheters.

KEY POINTS

Insertion Site and Equipment

1. The common sites of arterial line insertion are the radial, femoral, and dorsalis pedis arteries. These arteries are superficial; covered only by skin, fascia, and fat; and are easily compressible.
2. The arterial line can be inserted using a simple catheter-over-needle arrangement (with or without a guidewire) or a set based on the Seldinger technique.

3. Guidewires should only be used when back flow of blood is present to avoid arterial damage.
4. Doppler or ultrasound can be helpful for difficult line insertion.
5. Errors in pressure measurement can arise from incorrect zeroing, overshoot, or damping.
6. When zeroing, the height difference between the arterial puncture site and the transducer must be taken into account.

KEY POINTS—cont'd

7. Overshoot and damping affect the systolic blood pressure more than the diastolic or mean pressure.
8. The fast flush test can be used to assess underdamping or overdamping.
9. Low-concentration heparin is the most common arterial line flush solution. Sodium citrate, papaverine, and saline have been used.

Vascular and Local Complications

1. Arterial obstruction is very common after catheter insertion although rarely detrimental.
2. Obstruction may be mechanical from the catheter or result from thrombosis.
3. Small arteries, female gender, and shock are risk factors for thrombosis.
4. Pain, weakness, changes in sensation, pallor, or decreased temperature should prompt immediate catheter removal.

Erroneous Blood Tests

1. The majority of blood tests obtained from the arterial line will be accurate.
2. The type of flush solution used may interfere with certain tests.
3. Particular care should be taken when interpreting the activated partial thromboplastin time and blood culture results in samples drawn from the arterial line.

4. Five to six times the deadspace volume might be required for accurate tests, which may be reinfused with appropriate precautions.

Anemia, Heparin-Induced Thrombocytopenia, and Infection

1. Anemia can result from the volumes of blood drawn from the arterial line. Simple steps can reduce this blood loss.
2. Heparin-induced thrombocytopenia (HIT) is a syndrome defined by thrombocytopenia and thrombotic events in the presence of heparin/platelet factor 4 (PF4) complex antibodies.
3. Even very small doses of heparin can induce or maintain HIT. All sources of heparin should be removed if HIT is suspected, including from arterial line flush.
4. The rate of bloodstream infections related to the arterial line has been estimated to be 1.7 per 1000 catheter-days, whereas 1.5 in 100 arterial catheters causes infection.
5. Insertion technique, duration of cannulation, site, insertion site, and frequency of set changes have all been related to an increased infection risk.
6. Comparisons of studies relating to infectious risk are difficult owing to differing definitions of infection and study methodology.
7. The Centers for Disease Control and Prevention recommends: Use a >0.5% chlorhexidine in 70% alcohol solution for skin cleaning, do not change arterial catheters routinely, change the pressure monitoring sets and transducers every 96 hours, and do not use dextrose-containing flush solution.

ANNOTATED REFERENCES

- Gardner RM. Direct blood pressure measurement—dynamic response requirements. *Anesthesiology* 1981;54:227-236.
A description of natural frequency and damping as related to the arterial line. Also included are a description of the fast flush test and its interpretation. Graphs, formulas, and recommendations are provided to obtain a well-balanced system and accurate blood pressure readings.
- Martin C, Saux P, Papazian L, et al. Long-term arterial cannulation in ICU patients using the radial artery or dorsalis pedis artery. *Chest* 2001;119:901-906.
This is a prospective observational study examining the complications of dorsalis pedis (DPA) (131 patients) versus radial artery (RA) cannulation (134 patients) in consecutive groups of patients. The study showed that arterial occlusion was very common (present to some degree in 63% of the DPA patients and 76% of the RA patients) but clinically asymptomatic.

BEFORE PROCEDURE

Indications

- Need for continuous monitoring of pulmonary artery (PA) and right atrial (RA) pressures, cardiac output, and mixed venous oxygen saturation (SvO₂) providing that
 - The data collected will help in the management of the patient
 - The same measurements cannot be reliably obtained by a less invasive method

Contraindications

- Absolute contraindications
 - Tricuspid or pulmonary valve endocarditis
- Relative contraindications:
 - Tricuspid or pulmonary valve mechanical prosthesis
 - Right heart mass (thrombus and/or tumor)
 - Complete left bundle branch block (risk of complete heart block)

Equipment

- Sterile gowns, gloves, and masks
- 8F to 9F gauge introducer
- Sterile saline solution for flushing
- Volume-limited syringe for pulmonary artery catheter (PAC) balloon
- Pressure monitor transduction system and connector tubing

ANATOMY

The inflated balloon of the PAC facilitates the catheter progression through a branch of the PA. The distal lumen of the PAC measures the pressure downstream. It is assumed that there is a continuous column of blood between the distal lumen and the left ventricle (LV), and therefore the PA balloon-occluded pressure (PAOP) is equal to left ventricular end-diastolic pressure (LVEDP). PAOP reflects the pressure where the nonflowing blood (in the obstructed vessel) joins the blood flowing from the nonoccluded branches of the pulmonary artery. PAOP is actually intermediate between pulmonary capillary pressure and left atrial (LA) pressure. There are conditions, however, in which this theoretical continuous column of blood is interrupted, and in these circumstances PAOP no longer reflects LVEDP.

PROCEDURE

See Video E5-1.

- Check the patient's electrocardiogram (ECG), coagulation profile, and serum electrolyte panel. One should consider correcting major clotting disorders. If the patient already has a temporary pacemaker, it may be better to place the catheter under radiographic guidance to avoid dislodging the pacemaker.
- Inflate the catheter balloon as a test prior to catheter insertion.
- Connect the distal lumen to the pressure-monitoring system, and flush all lumens with sterile saline solution.
- Zero-reference the pressure transducer to the mid-chest position.

- Slide the protective sleeve onto the catheter to maintain sterility for further manipulations.
- Place sterile field.
- Give local anesthesia.
- Insert introducer into a central vein, preferably the internal jugular or subclavian, using the Seldinger technique.
- Pass the catheter through the hemostatic valve of the introducer.
- Inflate the balloon once the catheter tip has passed about 15 cm.
- Advance the catheter for another 15 cm. It should pass into the right ventricle (RV) and give an RV pressure waveform (Fig. E5-1).
- Advance the catheter further to pass into the PA and finally to obtain a PAOP waveform.
- Once a PAOP waveform has been obtained, deflate the balloon to return to the PA waveform.
- Once the catheter is in place, check the position with a chest radiograph. In the vast majority of cases, the tip is in the right lung. The tip should be within 2 cm of the cardiac shadow.
- All pressures should be measured at end expiration, when alveolar pressure should be closest to atmospheric pressure.

Procedural Precautions

- Always have the PA trace displayed on the monitor.
- Never withdraw the catheter without first deflating the balloon.
- Do not insert large lengths of catheter without observing a pressure change, because this maneuver may lead to looping and knotting of the catheter.
- There may be difficulties in reaching the RV or PA owing to RA or RV dilatation, tricuspid regurgitation, or abnormalities of the central veins. An option may be to advance the catheter with the balloon partially deflated during inspiration, repositioning the patient in a head-up or right lateral position, or flushing the catheter with iced saline to make it more rigid.
- If the PAOP trace is obtained when the balloon is inflated with less than 1 mL of air, or if there is a progressive elevation of pressure when the balloon is inflated ("overwedging"), the catheter tip is too advanced and should be withdrawn by a few centimeters to decrease the risk of PA rupture/infarction.

AFTER PROCEDURE

Postprocedure Care

- The PAC can be kept in situ for several days but should be removed as soon as it is no longer required for patient care.
- Balloon rupture can be identified by failure to wedge and failure of the syringe plunger to spontaneously deflate the balloon.

Interpretation of Measured Pressures

See also Table E5-1.

- The PA waveform has a systolic and diastolic pressure with a dicrotic notch corresponding to closure of the pulmonary valve.
- The PAOP, like the central venous pressure (CVP), has a venous waveform with a, c, and v waves corresponding to LA contraction, closure of the mitral valve, and passive LA filling, respectively.
- The a wave coincides with the point of maximal filling of the LV and is, therefore, the value that should be used for measurement of

FIGURE E5-1 ■ Pressure traces as the pulmonary artery catheter is advanced.

TABLE E5-1

Interpretation of the Measured Pressure Variables

| CVP/RAP | PAP | PAOP | INTERPRETATION |
|-------------|------------|------------|---|
| Low/normal | Low/normal | Low/normal | Normal |
| Low/normal | High | High | Left heart failure (good right heart function) |
| Normal/high | High | Low | Pulmonary hypertension (e.g., COPD, ARDS, pulmonary embolism) |
| High | High | High | Hypervolemia (high CO) Global heart failure (low CO) Tamponade (low CO) |

COPD, chronic obstructive pulmonary disease; ARDS, acute respiratory distress syndrome; CO, cardiac output.

LVEDP. A large-amplitude a wave with an increase in measured PAOP suggests LV ischemia and decreased ventricular compliance.

- A large v wave on the PAOP trace represents mitral regurgitation or an acute volume load to the LA, as occurs with septal rupture. The PAOP level should be measured without consideration for this v wave.
- The RA pressure waveform can look like an RV waveform if there is significant tricuspid regurgitation.
- In cardiac tamponade, RA pressure and PAOP are high and similar as they equilibrate with pericardial pressures.
- A “dip-and-plateau” waveform may be seen in the RV pressure tracing in constrictive pericarditis, restrictive cardiomyopathy, RV infarction, and massive pulmonary embolism. This pattern is due to impaired ventricular filling during diastole.

Measurement of Cardiac Output with the PAC

- Cardiac output is measured using thermodilution.
- Measurement is based on the *indicator dilution principle*: when an indicator substance is added to a stream of flowing blood, the flow rate is inversely proportional to the mean concentration of the indicator at a downstream site. In the case of thermodilution, the indicator used is temperature, using either a bolus of cold injectate (cold thermodilution) or a thermal filament to generate heat (warm thermodilution).
- The old technique included a 10-mL bolus of room temperature 5% dextrose solution or saline injected over 4 seconds through the proximal port of the PAC. The thermistor proximal to the balloon then recorded the temperature change in the PA, and a temperature

time curve was displayed. The average of at least three curves was then obtained.

- Modern catheters provide a semicontinuous method in which a thermal filament is mounted on the PAC 14 to 25 cm from the tip. The filament intermittently generates pulses of heat, and the temperature change is recorded by the thermistor in the PA. These pulses of heat are pseudorandom to minimize the influence of other sources of temperature change such as infusions or respiratory fluctuations. The cardiac output is updated every 30 to 60 seconds and is time-averaged over the previous 3 to 6 minutes.

Complications

Complications that are unique to the PAC and not just due to insertion of a central venous catheter can be divided into those caused by placement and the longer term complications due to its presence:

- Placement
 - Common
 - Arrhythmias, most commonly premature atrial or ventricular contractions that are self-limiting and can occur on insertion or withdrawal of the catheter
 - Rare
 - Knotting of the catheter; a knot generally can be removed by placing a guidewire through the PAC to undo the loop or by pulling the loop tight against the introducer sheath and removing the whole unit.
 - Tricuspid pulmonary regurgitation or chordae tendineae rupture can occur if the catheter is withdrawn with the balloon inflated.
- Presence of the catheter
 - Common
 - Arrhythmias, most commonly premature atrial or ventricular contractions that are self-limiting and can occur on insertion or withdrawal of the catheter
 - Catheter-related infections
 - Rare
 - Pulmonary infarction due to catheter-related thromboembolism, obstruction of the pulmonary blood flow by the catheter tip, or prolonged inflation of the balloon. Usually without any consequences.
 - Endocarditis
- PA rupture occurs in less than 0.1% of cases, associated with a mortality of greater than 30%. Warning signs include hemoptysis, with shadowing on the chest radiograph. Diagnosis is confirmed by pulmonary angiography. Treatment consists of embolization or thoracotomy. Factors increasing the risk of rupture include pulmonary hypertension, advanced age, hypothermia, coagulation disorders, and distal positioning of the catheter.

OUTCOMES AND EVIDENCE

- Benefits of bedside PAC remain controversial, and insertion of a PAC cannot, per se, improve patient survival.
- Pulmonary artery catheters should not be inserted routinely but only in patients in whom the data collected will help in the patient's management and the same measurements cannot be obtained by a less invasive method.
- To be beneficial, data from the PAC must be collected, interpreted, and applied correctly.

■ BEFORE PROCEDURE

Indications

- Emergency reestablishment of an organized electrical rhythm
 - Hemodynamically unstable polymorphic ventricular tachycardia
 - Ventricular fibrillation
 - Pulseless ventricular tachycardia
 - Narrow or wide QRS complex tachycardia (ventricular rate >150) associated with hemodynamic instability, chest pain, or pulmonary edema
- Elective reestablishment of sinus rhythm
 - Atrial fibrillation
 - Atrial flutter
 - Hemodynamically stable ventricular tachycardia unresponsive to medical treatment
 - Others

Contraindications

- Specific advance directives (e.g., do not attempt resuscitation for cases of ventricular fibrillation)
- Digitalis toxicity–associated tachycardia
- Sinus tachycardia caused by various clinical conditions
- Rhythms not responsive to electric shock (e.g., multifocal atrial tachycardia)
- Atrial fibrillation or atrial flutter without proper anticoagulation or exclusion of atrial thrombi

Equipment

- Automated external defibrillator or manual defibrillator
- Proper age-adjusted pads or paddles

■ ANATOMY

The heart is located behind the sternum. Its base is at the level of the third intercostal space immediately to the right of the sternum, and its apex is at the level of the fifth intercostal space inferior, and usually just medial to the nipple. External cardioversion or defibrillation is attempted by delivering one or more electric shocks through the chest cavity for the purpose of passing an electric current of sufficient energy through the heart muscle to fully depolarize the atria (e.g., atrial fibrillation or atrial flutter) or the ventricles (e.g., ventricular fibrillation or ventricular tachycardia). Cardioversion should enable the natural or artificial cardiac pacemaker to resume control of the cardiac rhythm. Electrodes (paddles or pads) can be positioned on the anterior chest wall, with one electrode below the right clavicle lateral to the sternum and the other electrode below the breast tissue along the midaxillary line. Electrodes (e.g., pads or paddles that are more difficult) can also be positioned in an anteroposterior position, with the anterior electrode placed over the precordium and the posterior electrode at the right infrascapular location. For internal cardioversion or defibrillation, specially designed paddles are applied directly to the epicardial surface of the ventricles.

■ PROCEDURE

See Videos E6-1 and E6-2.

- For external elective cardioversion, many of the following steps may have to be shortened or circumvented in hemodynamically unstable patients (especially if unconscious), requiring rapid termination of life-threatening arrhythmia (e.g., ventricular fibrillation or pulseless ventricular tachycardia as part of cardiopulmonary resuscitation).
- Admit the patient to an appropriately equipped hospital area with the capability for monitoring cardiac rhythm, oxygenation, and vital signs, along with airway management and cardiopulmonary resuscitation.
- Fast the patient overnight or for at least 6 to 8 hours.
- Establish vascular access.
- Obtain an electrocardiogram.
- For sedation, consider using a short-acting anesthetic agent (e.g., midazolam, propofol, or etomidate) under the care of an anesthesiologist or similarly privileged anesthesia provided and adequate supportive personnel. An alternative to anesthesia is moderate sedation, in which the patient maintains consciousness but in a somnolent state. This has the advantage that it can be given by trained physicians without an anesthesiologist present.
- Attach monitor leads to the patient, and ensure proper display of the patient's rhythm.
- Place electrodes properly separated (as described under Anatomy). Apply coupling gel if using paddles; avoid smearing the gel over the chest wall to prevent current traversing superficially through the chest. In patients with permanent pacemakers or implantable cardioverter-defibrillators, place electrodes away from the device generator to avoid device malfunction. Consider reevaluating pacing thresholds in patients with permanent pacemakers and interrogation of implantable cardioverter-defibrillator function after cardioversion.
- Engage the synchronization mode, and identify markers on the R waves indicating adequate R-wave recognition. If necessary, adjust the gain of the monitor until markers appear on each R wave.
- Select the energy level to deliver the necessary current based on the patient's waveform, age, and arrhythmia. Organized rhythms with a simple reentry circuit (e.g., atrial flutter and monomorphic ventricular tachycardia) usually require less current than more complex rhythms (e.g., atrial and ventricular fibrillation).
- Press the charge button on the unit or paddles.
- If using paddles, apply approximately 12-kg pressure to each paddle.
- Press the discharge button on the unit or paddles simultaneously.
- Check the monitor. If the arrhythmia persists, increase the energy level according to the protocol for the specific rhythm.
- Reset the synchronization. Most units default to the unsynchronized mode (allowing immediate defibrillation if ventricular fibrillation ensues).
- Repeat the shock until the conversion of the arrhythmia or completion of the protocol.
- Deliver unsynchronized shocks only for ventricular fibrillation or pulseless ventricular tachycardia.

AFTER PROCEDURE

Postprocedure Care

- Obtain an electrocardiogram.
- Assess hemodynamic and respiratory status.
- Observe the patient until the recovery from anesthesia or sedation is complete.
- Consider hospital discharge if the procedure was elective.

Complications

- Cardioversion and defibrillation are relatively safe procedures with infrequent complications that may include
 - Induction of ventricular fibrillation if the electric shock is improperly synchronized

- Transient conduction abnormalities
- Myocardial dysfunction (after high-energy and repetitive delivery of electric shocks)
- Release of cardiac enzymes
- Pulmonary edema
- Embolization of thrombi formed within the cardiac chambers (e.g., atrial fibrillation and flutter)
- Respiratory depression associated with anesthesia or sedation

OUTCOMES AND EVIDENCE

- Sinus rhythm will be restored in a high percentage of patients.
- Underlying conditions may predispose certain patients to a recurrence of arrhythmias.
- Early defibrillation of ventricular fibrillation is associated with improved survival.

BEFORE PROCEDURE

Indications

- Treatment of symptomatic bradycardia
 - Sinus bradycardia
 - Second-degree or third-degree atrioventricular block
- Prophylaxis
 - Bradycardia-induced ventricular tachyarrhythmias (e.g., torsades de pointes)
 - Increased risk of advanced atrioventricular block (e.g., acute myocardial infarction, infective endocarditis, surgery in patients with underlying conduction defects)
- Overdrive pacing for termination of tachyarrhythmias
 - Supraventricular tachycardia
 - Ventricular tachycardia
- Improving hemodynamic function
 - Sequential atrioventricular pacing

Contraindications

- Specific advance directives (e.g., do not attempt resuscitation for cases of pulseless electrical activity)
- Asymptomatic bradycardia
- Severe hypothermia (risk of ventricular fibrillation)

Equipment

- Pacing catheter with pulse generator
- Transcutaneous electrodes with pacing unit (integrated with current cardioverter-defibrillators)

ANATOMY

The heart is located behind the sternum. Its base is at the level of the third intercostal space immediately to the right of the sternum, and its apex is at the level of the fifth intercostal space inferior, usually just medial to the nipple. Transcutaneous pacing can be performed by delivering electric impulses through the chest cavity to “capture” and drive the electrical activity of the heart. Electrodes can be placed on the anterior chest wall, with one electrode below the right clavicle lateral to the sternum and the other electrode below the breast tissue along the midaxillary line. Electrodes can also be placed in an anteroposterior configuration, with the anterior electrode placed over the precordium and the posterior electrode at the right infrascapular location. For transvenous pacing, the pacing catheter can be advanced through the brachial (antecubital), femoral, internal jugular (preferably right), subclavian (preferably left), or the right subclavian via supraclavicular access (experienced practitioner).

PROCEDURE

Transvenous Temporary Pacing

See Video E7-1.

- Admit the patient to an appropriately equipped hospital area with the capability for monitoring cardiac rhythm, oxygenation, and

vital signs, along with airway management and cardiopulmonary resuscitation.

- Obtain a 12-lead electrocardiogram (ECG).
- Attach monitor leads to the patient, and ensure proper display of the patient's rhythm.
- Perform the procedure under fluoroscopy if available and time permits; otherwise use the ECG and rhythm to guide placement.
- Establish vascular access under local anesthesia and full sterility, advancing a proper-size introducer sheath.
- Select pacing catheter contingent on approach. Catheters for use under fluoroscopy are semirigid (usually made of woven polyester) to facilitate maneuvering into position. Catheters designed for blind placement have a balloon at the tip to be floated into position. Transvenous pacing can also be accomplished using multipurpose pulmonary artery catheters built with up to five electrodes for right atrial and right ventricular pacing.
- Blind placement using a balloon-tipped catheter can be guided by the ECG. A V_1 lead of a conventional ECG is connected to the distal pole (cathode) of the pacing catheter and used to monitor a unipolar intracavitary electrogram. The catheter is floated, seeking the display of a right ventricular intracavitary electrogram point at which the balloon can be deflated, and the catheter advanced a few centimeters to position its tip in the right ventricular apex. Endocardial contact is confirmed by the development of an “injury” current characterized by prominent ST-segment elevation. The pacing electrode is connected to the pulse generator and used in the unipolar or bipolar configuration.
- Another, more practical, approach (that is preferred in emergency situations) is to advance the pacing electrode into the right ventricle and turn the pulse generator on in the asynchronous mode at a rate that exceeds the native rate. The pacing current is set between the default and maximum output, and the pacing electrode is maneuvered until capture occurs.
- A defibrillator should be available during insertion and afterward because life-threatening ventricular tachyarrhythmias may develop, especially if the pacing lead moves within the ventricular cavity.
- Leave a sterile sleeve around the catheter (available with most introducer kits) to facilitate subsequent repositioning if required.
- Obtain an anteroposterior and lateral chest x-ray to verify proper placement and exclude complications.
- Set pacing options as follows:
 - Determine the pacing threshold, and set the pacing output. For this purpose, set the pacemaker rate to exceed the spontaneous heart rate by 10 to 20 beats/min and the output to a level expected to capture 100% of the beats (i.e., 6 mA). Capture is verified on the ECG by identifying the presence of a spike (pulse) followed by a wide QRS complex. The output is reduced gradually until beats are no longer captured and then increased again to identify the minimal level at which 100% of the beats are paced; this is the threshold output. This threshold level should be less than 1 mA for ventricular pacing and less than 2 mA for atrial pacing in the unipolar and the bipolar configurations; otherwise, the lead must be repositioned. The output is set at about three times the threshold level for reliable capture.
 - Set sensitivity (range: 0.5–20 mV), allowing the native R wave to inhibit the pacemaker impulse when the generator is set in synchronous mode. The output is first set to its minimal level

(e.g., 0.1 mA) and the pacing rate to a value below the spontaneous heart rate. Starting from the maximal sensitivity (the lowest value; i.e., 0.5 mV), gradually decrease the sensitivity (increasing its value) until the unit stops sensing the R wave. For reliable inhibition, the sensitivity is set at about three times the sensitivity threshold (e.g., if the threshold is 3 mV, the level is set at 1 mV).

- The pacing rate for bradyarrhythmias is set according to physiologic needs, usually between 60 and 75 beats/min. Higher rates (800 beats/min) are available for overriding the pacing of ventricular or supraventricular tachyarrhythmias.
- Sequential atrioventricular pacing requires the placement of an additional lead or the use of a multipurpose pulmonary artery catheter along with a dual-chamber pulse generator. The individual chamber specifications for dual-chamber generators are similar, with the option of setting the AV pacing interval between 20 and 300 msec.

Transcutaneous Temporary Pacing

See Video E7-2.

- Transcutaneous pacing is noninvasive and can be used in emergency settings with ease and minimal delay while preparing for more definitive therapy. Alternatively, it can be used prophylactically.
- Pacing is limited to the ventricles (with minimal capability for atrial pacing), capture is not always attained, and tolerability may be poor.
- Place electrodes on the anterior chest wall or in an anteroposterior configuration as described under Anatomy. Place the negative electrode (i.e., cathode) anteriorly, close to the heart (typically over the palpable cardiac impulse or centered on a V_3 lead) to minimize the capture threshold. Place the positive electrode (i.e., anode) over the upper right region of the chest or the posterior chest wall between the bony spine and the inferior border of either the left or right scapula.
- Determine the pacing threshold as for transvenous pacing (described earlier), bearing in mind that the pacing threshold is much higher (20 to 140 mA), particularly in patients with emphy-

sema and pericardial effusion and in patients undergoing positive pressure ventilation. The pacing output is set 5 to 10 mA above the threshold. Pulse generators are designed to deliver high current levels (200 mA) with a longer pulse duration (20 to 40 msec) to facilitate capture and minimize patient discomfort.

- Ensure that capture occurs by demonstrating coincident pulse generation; do not rely on the ECG capturing artifacts from the skeletal muscle activity.

AFTER PROCEDURE

Postprocedure Care

- Obtain an ECG.
- Assess hemodynamic status.
- Monitor native and paced rhythms.
- Establish etiology, and institute definitive treatment.

Complications

- Pacemaker malfunction, defined as the failure to sense, capture, or both
- Ventricular dysrhythmias at the time of insertion
- Myocardial perforation with risk of cardiac tamponade
- Diaphragmatic stimulation
- Complications related to the vascular access (e.g., phlebitis, pneumothorax, arterial puncture, brachial plexus injury, pulmonary embolism, and sepsis)

OUTCOMES AND EVIDENCE

- Effective in pacing at the desired heart rate
- Transvenous pacing is more effective than transcutaneous pacing (lower capture rate)
- Lack of effectiveness for treatment of cardiac arrest due to asystole or pulseless electrical activity
- Temporary measures pending the resolution of the rhythm abnormality or permanent definitive pacemaker placement

■ BEFORE PROCEDURE

Indications

- Postcardiotomy failure (left ventricular assist device [LVAD])
 - Elevated left atrial pressure (LAP) and cardiogenic shock despite inotropic support and intraaortic balloon pump (IABP)
 - LAP >25 mm Hg
 - Cardiac index (CI) <2 L/min/m²
 - Severe left ventricular (LV) dysfunction on echocardiogram
 - Intractable ventricular arrhythmias
 - Ongoing myocardial ischemia despite revascularization
- Postcardiotomy failure (bilateral ventricular assist device [BiVAD])
 - Evidence of an elevated central venous pressure (CVP; >9 mm Hg) despite pulmonary afterload reduction
 - Evidence of severe right ventricular (RV) dysfunction on echocardiogram
 - Inability to provide adequate blood flow to fill the LVAD (if an LVAD is in place)
- Bridge to cardiac transplantation
 - Failure of optimal medical therapy that increases the risk of compromised life or end-organ function while awaiting cardiac transplantation
 - CI <2 L/min/m²
 - Mixed venous oxygen saturation <50% on optimal medical therapy
 - Ventricular arrhythmias
 - Severe symptoms at rest
 - Need for multiple inotropic agents
 - Lack of response to diuretic medications, with a rising creatinine
 - Pulmonary artery hypertension
 - Cool and constricted extremities reflective of poor perfusion
 - Low blood pressure, resting tachycardia, rales, and/or distended neck veins
 - Laboratory evidence of prerenal azotemia, hepatic dysfunction, or coagulopathy
 - Requirement for supplemental oxygen
- Bridge to bridge: in conditions of cardiogenic shock when indications for cardiac transplantation are not yet met but are potentially attainable
- LVAD versus BiVAD
 - Biventricular assist devices should be considered for
 - Intractable ventricular tachycardia or fibrillation
 - Cardiogenic shock requiring resuscitation with extracorporeal membrane oxygenation (ECMO)
 - Cardiogenic shock with multiorgan failure
 - Pulmonary edema despite maximal medical therapy
 - Chronic RV failure with ascites, low pulmonary artery pressure, severe hepatic or renal dysfunction, and tricuspid insufficiency
 - Severe acute respiratory distress syndrome
 - Giant cell myocarditis
 - Large anterolateral myocardial infarction with involvement of the anterior right ventricle
 - RV infarction

- Destination therapy
 - Indicated for patients who meet the above criteria for bridge to transplantation LVAD candidacy but who are not eligible for transplantation based upon age, obesity, renal dysfunction that will not tolerate immunosuppressive agents, or other comorbidities suggesting that the risk of transplantation is unacceptable
- Patients with advanced heart failure (HF) symptoms (New York Heart Association [NYHA] class IIIB or IV) who meet at least one of these criteria
 - Continued failure despite optimal medical management for at least 45 of 60 days
 - NYHA class III or IV status for at least 14 days and dependent on IABP for 7 days and/or inotropes for 14 days
 - Treated with angiotensin-converting enzyme (ACE) inhibitors or beta-blockers for at least 30 days and found to be intolerant of these medications
 - Maximal oxygen consumption (VO₂ max) ≤14 mL/kg/min or ≤50% predicted VO₂ max with exercise testing (unless testing is contraindicated because of class IV status)

Contraindications

- Postcardiotomy failure
 - Sepsis
 - “Stone heart” or lack of any innate cardiac function
 - Age >70 years
 - Condition in which recovery is not anticipated and the patient is not a candidate for cardiac transplantation
- Bridge to transplantation
 - Patient is not a candidate for cardiac transplantation
 - Sepsis
 - End-organ damage is not likely to recover
 - Severe impairment of neurologic function
 - Severe chronic obstructive pulmonary disease
 - Procoagulation abnormalities, with previous venous or arterial thrombosis despite anticoagulation therapy
 - Pregnancy
 - Inability or refusal to receive blood transfusions
 - Technical obstacles that pose an inordinately high surgical risk
- Destination therapy
 - Same as for transplantation, other than the requirement for cardiac transplantation candidacy
 - Lack of social or family support that allows for home discharge
 - Inability to comprehend plans for postoperative LVAD training
 - Expected need for prolonged biventricular support
 - Severe symptomatic peripheral vascular disease
 - Intolerance to anticoagulant or antiplatelet therapies or any other peri- or postoperative therapy the patient will require based upon his or her health status
 - Psychiatric disease, irreversible cognitive dysfunction, or psychosocial issues likely to impair compliance with protocols and LVAD management

Equipment

- Postcardiotomy
 - IABP
 - ABIOMED AB/BVS 5000 (LVAD and BiVAD)
 - Tandem Heart
 - Thoratec CentriMag (LVAD and BiVAD)
 - Thoratec PVAD (LVAD and BiVAD)
- Bridge to transplantation
 - Thoratec PVAD (LVAD and BiVAD)
 - Heartmate II
 - Heartware HVAD
 - DuraHeart
 - Levacor
 - CardioWest Total Artificial Heart
- Destination therapy
 - Heartmate II
 - Heartware HVAD

PROCEDURE

- Intraoperative preparation and evaluation
 - Lines: arterial, venous, Swan-Ganz (continuous cardiac output type for continuous-flow LVADs)
 - Preoperative echocardiogram assessment
 - LV thrombus
 - Interatrial septal defect or patent foramen ovale (PFO)
 - Aortic insufficiency
 - Tricuspid insufficiency
 - Right ventricular function
 - Hemodynamic control
 - Management and preservation of perfusion pressure for right ventricle and coronary arteries utilizing α -agonists
 - Preoperative thromboelastogram to assess coagulopathy and the need for transfusion products
 - Cautious volume management
 - Cannulation for cardiopulmonary bypass
 - Distal ascending aortic site for inflow
 - Standard two-stage venous cannula for drainage (for standard LVAD)
 - Biatial cannulation for BiVAD or if tricuspid repair or PFO closure is required
 - Apical LV cannulation achieved for LVAD
 - Apical cannulation performed according to protocol dictated by each individual VAD brand
 - Preperitoneal pocket required for some LVADs; otherwise, a subcostal tunnel is created as needed
 - Aortic outflow graft sewn end-to-side for outflow
 - RVAD cannulation via the right atrial appendage
 - RVAD return to the pulmonary artery via arterial cannula
- Closure of pericardium preferred
- Adequate chest tube drainage from mediastinum and pleural spaces

AFTER PROCEDURE

Postprocedure Care

- Hemodynamic and volume control
 - Blood pressure maintenance is critical for RV function.
 - Adequate inotropic support is needed for the right ventricle.
 - Appropriate blood product replacement should be given, guided by thromboelastogram.
 - Adequate blood pump flow is determined by adequate CI (at least 2.4 L/min/m²).
 - In most cases, decompression of the LV should not be so great as to cause right-to-left interventricular septal shift. Mitral regurgitation should be reduced and the aortic valve open occasionally.
 - CVP should be maintained between 8 and 12 mm Hg.

- Intensive care unit management
 - Maintain positive pressure ventilation until mental status and pulmonary function allow for extubation.
 - Remove chest tubes as soon as possible.
 - Begin anticoagulation for the ventricular assist device (VAD) with heparin after 24 hours (if bleeding is less than 50 mL/h), and convert to warfarin when the patient is taking oral fluids.
 - Broad-spectrum antibiotics should be continued for 4 to 5 days.
 - Active physiotherapy should be carried out, with emphasis on pulmonary toilet and incentive spirometry.

Complications

- Common
 - Bleeding: mediastinal, wounds, driveline sites, gastrointestinal
 - RV dysfunction
 - Infection: driveline-associated (especially at exit site), pulmonary, urinary tract
- Infrequent
 - Neurologic events
 - Arrhythmias
 - Hemolysis
 - Psychiatric
- Serious, rare complications
 - Device malfunction

OUTCOMES AND EVIDENCE

Successful clinical evaluation of the Thoratec PVAD led to U.S. Food and Drug Administration (FDA) approval for bridge to transplantation (BTT) indication in 1992. Twenty-four patients (62%) required support with an LVAD alone, and 15 (38%) required BiVAD support. Survival from support to successful outcomes was 70% for BTT and 67% for postcardiotomy recovery.

The HeartMate II (Thoratec Corporation, Pleasanton, California) is a continuous-flow rotary pump with an axial design, which is representative of the second generation of LVAD technology in clinical use in the United States. Successful clinical evaluation of the Thoratec pVAD led to FDA approval for BTT indication in 1992. Of the 133 patients receiving support with the HeartMate II device, the principal efficacy outcomes were observed in 100 patients (75%). The median duration of support was 126 days (range, 1-600). The survival rate during support was 75% at 6 months and 68% at 12 months. There was significant improvement in distance walked between baseline and 6 months, with over 50% of patients experiencing an improvement in the 6-minute walk distance to over 200 meters.

In 1998, the National Heart, Lung, and Blood Institute funded the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial. REMATCH was a pivotal trial designed to assess morbidity, mortality, and functional outcomes in a homogeneous cohort of patients with advanced heart failure ineligible for cardiac transplantation. Survival rates at 1 year (52% vs. 25%, $P = 0.002$) and 2 years (23% vs. 8%, $P = 0.09$) were superior (significantly) in the VAD patients compared with the survival rates in those patients randomized to medical therapy.

Following the original REMATCH publication, Park and colleagues analyzed the outcomes of the trial, based upon the era of enrollment. Despite more high-risk characteristics, patients enrolled in the latter half of the study had significantly higher 1- and 2-year survival rates than those enrolled during early experience with the VAD. A similar improvement in survival outcomes was seen in the postapproval registry, with a 56% 1-year survival rate. Improved outcome with VAD use and experience is a consistent observation, which was also evident in the continued access protocol cohort versus primary cohort in the HeartMate II BTT trial. Demonstration of improved survival outcomes in patients with preimplant risk profiles similar to or worse than those enrolled in the initial randomized trial suggests that refinement of pre- and postoperative management and greater experience with mechanical circulatory support are important

factors in determining survival and functional improvements after VAD implantation.

The HeartMate II DT Pivotal Trial evaluated 200 patients with NYHA class IIIb-IV symptoms, ejection fraction (EF) <25%, and VO_2 max ≤ 14 mL/kg/min or treatment with intravenous inotropic agents for at least 14 days or an IABP for 7 days. The patients were randomized

to receive a HeartMate II (n = 134) or a HeartMate XVE (n = 66). There was a greater than fourfold increase in the percentage of HeartMate II patients who successfully reached the primary endpoint (46% vs. 11%, $P < 0.001$). Patients randomized to the HeartMate II had 1- and 2-year survival rates of 68% and 58%, compared with 55% and 24% in patients who received the HeartMate XVE.

■ PREPROCEDURE

Indications

- Pericardial tamponade
 - Pericardiocentesis is the first treatment option in patients with overt tamponade because only the removal of fluid allows normal ventricular filling and restores adequate cardiac output.
 - If the patient is hemodynamically stable, the procedure should be performed within 12 to 24 hours from diagnosis, after obtaining laboratory results including the blood counts.
- Pericardial effusion without hemodynamic compromise
 - Persistent (more than 1-week treatment) large pericardial effusion (>20 mm anterior plus posterior space in echocardiography in diastole).
 - Suspected bacterial or tuberculous pericarditis
 - Elective pericardiocentesis is warranted in patients with suspicion of purulent pericarditis.
 - Purulent pericarditis should be managed aggressively, as death is inevitable if untreated, whereas with comprehensive therapy 85% of cases have been reported to survive the episode and have a good long-term outcome.
 - Treatment consists of systemic antibiotic therapy and complete evacuation of the effusion. Surgical drainage usually is required, because percutaneous drainage alone is not able to completely evacuate the effusion, which is often rich in fibrin and can be loculated and associated with dense adhesions. An alternative and less invasive method, which can be used to completely evacuate purulent effusions, thus controlling sepsis and avoiding the evolution to constrictive pericarditis, consists of pericardial drainage associated with intrapericardial infusion of streptokinase. Fibrinolytic therapy can enhance the removal of material that would otherwise be too viscous or particulate to be removed by tube drainage. This treatment should be considered before undertaking surgery.
- Suspected neoplastic effusion
- Pericardiocentesis for diagnostic purpose in mild or moderate effusions (<20 mm) should be confined to selected cases.
 - Pericardiocentesis with a diagnostic purpose (except in cases of suspected neoplastic, tuberculous, or purulent pericarditis) is not justified in the majority of cases for the following reasons: (1) low diagnostic power; (2) the underlying pathology is often already known or identifiable by different non-invasive tests; (3) viral pericarditis is usually self-limiting, and it only requires an antiinflammatory treatment; (4) high procedural risk.

Contraindications

- Urgent pericardiocentesis or drainage of pericardial effusion is indicated for each patient with established diagnosis of cardiac tamponade and hemodynamic shock.
- Aortic dissection and postinfarction rupture of the free wall are contraindications to pericardiocentesis and indications for urgent surgical drainage. Only when surgical management is not immediately available or the patient is too unstable, pericardiocentesis and

controlled pericardial drainage of very small amounts of the hemo-pericardium can be attempted to temporarily stabilize the patient in order to maintain blood pressure at ~90 mm Hg.

- Relative contraindications include uncorrected coagulopathy, anticoagulant therapy, and thrombocytopenia (PLTc < 50,000/mm³), and small, posterior, and loculated effusions.
 - The alterations of coagulation can be corrected using:
 - Fresh frozen plasma or platelets (may be time consuming)
 - Recombinant human factor VIIa, which may be effective in a shorter time.
 - Vitamin K + prothrombin complex concentrate

Equipment

- Echocardiography
- Multiangle bracket, to be assembled on the probe, (biopsy starter kit for GE 3S, 3S-RS, M3S, and M4S transducers [CIVCO USA, Kalona, IA])
- Needle-guide kit with sterile sheath and sterile echo-gel (Ultra Pro II needle guide [CIVCO USA, Kalona, IA])
- 14- to 16-gauge Teflon-sheathed needle (technique A)
- 18-gauge, 9-cm needle on a syringe for apical approach (technique B)
- 18-gauge, 15-cm needle, included in the PeriVac set (Boston Scientific USA, Marlborough, MA) for subxiphoid approach
- J-tipped guidewire
- 6F to 8F dilator
- Drainage catheter: pigtail angiocatheter 6F to 8F or pericardiocentesis set (PeriVac)
- Disposable flushing system to maintain the patency of the system

■ ANATOMY

The pericardium is a fibroserous sac that contains the heart and the origin of the main vessels. The pericardium is composed of two layers, the visceral pericardium, a monolayer membrane of mesothelial cells that is adherent to the epicardial surface of the heart, and the fibrous parietal layer that surrounds most of the heart. The pericardial space normally contains 25 to 50 mL of fluid in adults. If the amount of fluid increases, the pericardium is not immediately distensible, even though stress relaxation may occur within minutes from the beginning of the increase in pericardial pressure. If the fluid accumulates slowly, over weeks or months, the pericardium can increase in size to a maximum capacity of 1 to 2 L. The heart, and therefore the pericardium, is located at the center of the mediastinum, partially covered by the lungs; by the sternum and by the costal cartilages of the third, fourth, and fifth ribs; and by intercostal muscles. About two-thirds of the heart is located on the left side of the chest. The heart rests on the diaphragm. The pericardium is innervated by the vagus nerve, by the left recurrent laryngeal nerve, by the esophageal plexus, and it also has rich sympathetic innervation from the stellate and first dorsal ganglia and the cardiac, aortic, and diaphragmatic plexuses. When performing pericardiocentesis, close attention should be paid to avoid damaging the internal thoracic artery, which runs behind the sternal end of the costal

FIGURE E9-1 ■ Projection of cardiac area on the anterior thoracic wall.

cartilages, and the vascular bundle at the inferior margin of each rib (Fig. E9-1).

■ PROCEDURE

Echo-Guided Technique (A)

- Perform a two-dimensional and Doppler study to assess the size, distribution, and hemodynamic effect of the effusion.
- Place the patient in a semi-reclining position, at an angle of about 30 degrees, and slightly rotated leftward to enhance fluid collection in the infero-anterior part of the chest.
- Ensure that a central venous catheter is in place. The catheter is essential for monitoring right atrial pressure and permitting the rapid infusion of fluids and drugs as indicated.
- Continuous arterial pressure monitoring is indicated to detect the presence of pulsus paradoxus and to rapidly detect and correct sudden hemodynamic instability.
- Medical management:
 - In the unstable patient with hypotension and tachycardia, during preparation for pericardiocentesis, measures aimed to stabilize the patient should be instituted. Intravenous fluid administration is the best treatment option before and during drainage. In stable patients without low systolic blood pressure (>100 mm Hg) this treatment is not useful, and it could be dangerous reducing the cardiac output.
 - Intravenous administration of diuretics is contraindicated and could be fatal in patients on the edge of their compensatory mechanism in tamponade.
 - Both dopamine and dobutamine improved hemodynamics in cardiac tamponade; dobutamine has greater beta activity and therefore it may be considered preferable. However, the usefulness of inotropes is generally limited because endogenous adrenergic stimulation is already enhanced under tamponade conditions, and ejection fraction is preserved, but stroke volume is critically depressed.
 - Packed red cell units should be readily available before starting nonemergency procedures.
- Respiratory management
 - Pulse oximetry and supplemental O₂ should be warranted.
 - Influence of respiratory parameters: spontaneous versus mechanical ventilation and PaCO₂ levels significantly influence the evolution of pericardial tamponade. Pericardial pressure decreases 3 to 6 mm Hg when PaCO₂ decreases to 24 mm Hg; conversely, pericardial pressures increase 2 to 4 mm Hg when

PaCO₂ reaches 57 mm Hg. Increased intrathoracic pressures during the inspiratory phase of mechanical ventilation can decrease cardiac output up to 25% in patients with tamponade. To avoid further haemodynamic compromise, patients with suspected cardiac tamponade should not receive positive-pressure ventilation unless absolutely necessary.

- After appropriate disinfection of the operative field, local anesthesia of the skin is obtained by injecting with 2% lidocaine subcutaneously.
- The trajectory of the needle is defined by the angle between the probe and the chest wall. Ultrasound does not cross aerial spaces. Therefore, if cardiac structures are identified, there is no lung tissue interposed between the probe and the pericardium.
- The proper landmark for needle insertion corresponds to the area where the pericardial space is closest to the probe and the fluid accumulation is maximal; this site is para-apical more often than subxiphoid. The subcostal route is less frequently used because it requires a longer path to reach the fluid. It passes anterior to the liver capsule and is directed toward the right chamber of the heart.
- The optimal needle trajectory should be transfixed in the operator's mind and then a 14- to 16-gauge Teflon-sheathed needle with an attached saline-filled syringe is advanced in the direction of the fluid-filled space.
- Para-apical approach: insert the needle at 3 to 5 cm from the parasternal border (to avoid the internal thoracic artery), and close to the superior edge of the rib (to avoid the intercostal artery).
- Subxiphoid approach: direct the needle posteriorly until the tip passes posterior to the bony cage. Press the hub of the needle toward the diaphragm and advance the needle with a 15-degree posterior tilt, either directly toward the patient's head or toward the right or left shoulder.
- When fluid is aspirated, the needle should be advanced approximately 2 mm farther. The sheath should be advanced over the needle and the steel core withdrawn.
- If bloody fluid has been aspirated or if the position of the sheath is questionable, the position of the catheter can be confirmed by injecting 5 mL of agitated saline through the sheath. The bubbles in the solution provide a contrast effect that can be observed by two-dimensional echocardiography. Thus, if contrast agent appears in the pericardial space, the procedure can be continued.
- A guidewire should be advanced through the sheath, and then the sheath should be removed over the guidewire.
- A small incision should be made at the entry site, followed by introduction of a dilator (6F to 8F) over the guidewire. Predilatation of the chest wall passage facilitates subsequent insertion of the introducer sheath-dilator (6F to 8F).
- The guidewire and the dilator should be removed and only the sheath left in the pericardial sac. A pigtail angiocatheter should be inserted through the introducer sheath and the fluid aspirated.

Real-Time Echo-Monitored Procedure (B)

(This is the technique preferred by the authors.)

See Video E9-1.

- A different approach utilizes a needle carrier mounted on the transducer to advance the needle to the pericardial space under continuous visualization.
- Patient's preparation and supportive management are the same as those described earlier.
- Mount the bracket on the probe to support the needle-guide kit and to allow a real-time echo-monitored procedure. The bracket supports the needle with different angles, and the operator can choose between a closer angle for the subcostal approach and a wider angle for the apical approach (Fig. E9-2).
- Cover the probe with the sterile sheath and mount the needle-guide kit on the sheathed probe (Fig. E9-3).
- Once the optimal position is found and the pericardiocentesis procedure is started, the echocardiography probe should not be

FIGURE E9-2 ■ Echocardiographic probe with bracket, needle guide, and syringe.

FIGURE E9-3 ■ After bracket is mounted, probe is protected by sterile wrap.

more mobilized to avoid tearing the tissue. The execution of the technique with two operators can be useful to minimize this risk; one can firmly hold the probe, and the other can advance the needle. The needle (SDN 18-gauge, 9-cm Cook for apical approach, or the needle included in the PeriVac set for subxiphoid approach) is connected to a syringe for constant gentle aspiration and is slowly introduced through the tissues until there is echographic visualization of the tip (Fig. E9-4, A-C).

- When the needle tip is observed on the echo screen in the pericardial space and fluid is freely aspirated, the syringe is disconnected, and a J-tipped guide is inserted (Fig. E9-4, D).
- The technique is summarized in Figure E9-5.
- Remove the needle and make a small skin incision at the site of insertion.
- The drainage catheter (a pigtail angiocatheter 6F to 8F or pericardiocentesis set [PeriVac]) is subsequently introduced along the guidewire, according to the Seldinger technique, after introducing a 6F to 8F dilator over the guidewire.
- Completely aspirate the pericardial effusion by syringe suction, and connect the catheter to a disposable flushing system that infuses saline solution at a rate of 3 mL/h to maintain the patency of the system.

- In patients with very large pericardial effusion (>1 L), quick emptying of the pericardial sac may cause (in very rare cases) an acute pulmonary edema. In these patients, it may be advisable to limit aspiration to 1 L every 24 hours.

AFTER PROCEDURE

Postprocedure Care

- After the procedure, perform a chest radiography to exclude the presence of pneumothorax or pneumopericardium.
- Repeat aspiration by syringe every 4 to 6 hours.
- Remove the catheter once the drainage has decreased to less than 25 to 30 mL in 24 hours.
- Pericardial drainage for 24 to 72 hours is sufficient to avoid recurrence of pericardial tamponade in the majority of cases.
- It is important to empty the pericardial sac as completely as possible, leaving the catheter in place up to 72 hours (or more) if the fluid has a rate of accumulation greater than 30 mL in 24 hours.
- The omission of extended catheter drainage is an important independent predictor of recurrence.
- Reaccumulation of pericardial fluid is common in patients with malignant pericardial effusions (40%-70% recurrences rate without specific treatment). In these patients, several measures have been suggested to prevent recurrence of tamponade. These approaches include (1) complete evacuation of the fluid, (2) prolonged pericardial drainage, and (3) systemic antineoplastic treatment as baseline therapy. Other suggested measures are intrapericardial instillation of sclerosing and cytotoxic agents tailored to the type of tumor, radiation therapy in patients with radiosensitive tumors (i.e., lymphomas and leukemias), and pericardiectomy.
- Perform a complete echocardiographic study in all patients before removing the catheter and before the discharge from the ICU or coronary care unit.

Complications

- Common
 - Puncture of cardiac chambers (1.5%)
 - Pneumothorax (1%)
 - Pleuropericardial fistulas (0.8%)
 - Arrhythmias (usually vasovagal bradycardia)
- Infrequent
 - Laceration of coronary arteries or intercostal vessels
 - Bacteremia
 - Pneumopericardium
- Serious, rare complications
 - Death (0.1%-0.5%)
 - Chamber laceration requiring surgery

In a series of 53 pericardiocenteses performed under continuous echocardiographic visualization (technique B), no major complications occurred, no perforations or ruptures of cardiac chambers were reported, and the incidence of minor complications was 3.7%.

OUTCOMES AND EVIDENCE

- Randomized studies comparing different techniques do not presently exist.
- Pericardiocentesis-related mortality and serious complications are low when the procedure is performed by trained professionals following consolidated techniques.
- Percutaneous pericardiocentesis has been performed for many years using the blind subxiphoid approach. This technique is associated with high incidence of morbidity and mortality, and using electrocardiographic needle monitoring does not lead to significantly better outcomes. Accordingly, blind approaches are no longer justified.

FIGURE E9-4 ■ Two-dimensional echocardiographic image (apical four-chamber view) during needle introduction through tissues. **A**, Detection of pericardial effusion. **B**, Visualization of needle tip. **C**, Needle is advanced through tissues. **D**, Needle enters pericardial space and guidewire is introduced. LV, left ventricle; RV, right ventricle. (From Maggiolini S, Bozzano A, Russo P, et al: Echocardiography-guided pericardiocentesis with probe-mounted needle: report of 53 cases. *J Am Soc Echocardiogr* 2001;14:821-824.)

FIGURE E9-5 ■ Representation of pericardiocentesis using the apical approach. The pericardial needle is continuously monitored by apical four-chamber echocardiographic view while entering the pericardial space. When the pericardial effusion is reached, a guidewire is introduced in the pericardial space.

■ PARACENTESIS: BEFORE PROCEDURE

Indications

- Paracentesis is the insertion of a needle or catheter into the peritoneal cavity for the purpose of aspirating peritoneal fluid. It is most often indicated for diagnostic or therapeutic evacuation of ascites.
- Diagnostic indications
 - New-onset ascites: fluid evaluation to help determine etiology, differentiate transudate versus exudate, detect the presence of cancerous cells, or address other considerations
 - Differentiate between suspected spontaneous or secondary bacterial peritonitis
- Therapeutic indications
 - Respiratory compromise secondary to ascites
 - Abdominal pain or pressure secondary to ascites (including abdominal compartment syndrome)

Contraindications

- Absolute contraindication
 - Acute abdomen that requires surgery
- Relative contraindications
 - Inadequate volume of ascites on imaging (e.g., ultrasound)
 - Uncorrected hypovolemia
 - Severe uncorrected thrombocytopenia (platelet count < 20,000/ μ L) or coagulopathy (international normalized ratio [INR] > 2.0)
 - Pregnancy
 - Distended urinary bladder
 - Abdominal wall cellulitis
 - Distended bowel
 - Intraabdominal adhesions

Equipment

- Ultrasound machine
- Local anesthetic
- Chlorhexidine prep
- Sterile towels, gloves
- 18- or 20-gauge, 2- to 3-inch needle
- 20- to 50-mL syringe
- 14- to 16-gauge cannula-over-needle
- 8.5F 40-cm polyurethane pigtail catheter with guide wire
- 2-0 polypropylene suture

■ ANATOMY

The site for paracentesis is in the abdomen, lateral to the rectus muscle in the lower quadrant midway between the umbilicus and the anterior superior iliac spine, avoiding prior surgical incisions. Ultrasound guidance is recommended to identify the site of the largest volume of ascites and reduce the chance of injury to the intestines.

■ PROCEDURE

See Video E10-1.

- The patient should be supine. Bedside ultrasonography can be a valuable aid for localizing the largest collection of ascites and

avoiding injury to the bowel and should be employed routinely. The patient should void or have a urinary bladder drainage tube inserted before the procedure. The area is cleansed, draped, and anesthetized.

- When a small volume of ascitic fluid is needed for diagnostic studies, an 18- or 20-gauge, 2- to 3-inch needle attached to a 20- to 50-mL syringe is inserted into the abdomen lateral to the rectus muscle in the lower quadrant, midway between the umbilicus and the anterior superior iliac spine, avoiding prior surgical incisions. The skin is retracted caudad while inserting the needle. When fluid is aspirated, the needle is stabilized, and the fluid sample is obtained by syringe. After removal of the needle, the skin is released, causing the entrance and exit needle sites to form a “Z-track” that reduces the chance of ascitic fluid leakage.
- For large-volume paracentesis, a 14- to 16-gauge cannula-over-needle is employed. Once the fluid is aspirated into the syringe, the needle is removed, leaving the plastic catheter in place, which is attached to plastic tubing and a vacuum canister. Usually, 4 to 6 L of ascites can be safely removed, although larger volumes have also been obtained.
- If it is necessary to place a catheter into the peritoneal cavity, a guide wire should be inserted into the peritoneal cavity through the needle; an 8.5F 40-cm polyurethane pigtail catheter should be guided into the peritoneal cavity over the wire and sutured in place.
- The aspirated fluid should be submitted for a cell count, absolute polymorphonuclear neutrophil count, albumin, total protein concentration, Gram stain, and cultures. Optional studies, based on clinical suspicion, may include glucose concentration, amylase concentration, lactate dehydrogenase concentration, bilirubin concentration, and cytology.

■ AFTER PROCEDURE

Postprocedure Care

- The patient should be closely monitored for complications (see later), especially bleeding and peritonitis.
- If a pigtail catheter is left in place, it should be attached to a collection bag and monitored for bleeding or the drainage of succus.

Complications

- Common
 - Hypotension
 - Hypotension after paracentesis in cirrhotic patients can be associated with a worsening of arteriolar vasodilation.¹ In the first few hours after large-volume paracentesis, there is a reduction in the plasma levels of renin and aldosterone, an increase in the atrial natriuretic peptide concentration, a reduction in the cardiac filling pressures, and an increase in the cardiac index.
 - However, after 12 to 24 hours, these changes reverse, reflecting effective hypovolemia. Infusion of intravenous colloids, specifically albumin, has been shown to attenuate the hemodynamic consequences of paracentesis and the associated neurohumoral alterations.² However, no large randomized study has shown that routine expansion of plasma volume with a colloid solution confers a survival advantage.

- Infrequent
 - Bleeding
 - The incidence of significant hemorrhage from this procedure is about 1%, despite the fact that over 70% of patients have clotting parameter abnormalities.³ Therefore, it is usually unnecessary to normalize the prothrombin time before proceeding.⁴
- Serious complications (e.g., bowel perforation) are rare (0.1%)³
 - Peritonitis
 - Bowel injury
 - Injury to the bladder
 - Injury to the epigastric vessels

OUTCOMES AND EVIDENCE

- Determining the etiology of ascites is based on the patient's history, physical examination, liver function tests, ultrasonography, and ascitic fluid analysis. Abdominal paracentesis and ascitic fluid analysis should be an early step in the workup of patients with new-onset ascites. Paracentesis is also important to diagnose infection of the ascitic fluid (i.e., peritonitis).
- Development of ascites is a common complication of cirrhosis, being more frequent than either encephalopathy and variceal hemorrhage in these patients. The median survival of cirrhotic patients with ascites is 2 years.⁵ Other causes of ascites besides cirrhosis include malignancy, heart failure, tuberculosis, renal failure, and pancreatic disease.
- The mainstays of treatment of ascites secondary to cirrhosis involve dietary sodium restriction (2 g/d) and oral diuretics (e.g., spironolactone and furosemide).
 - The underlying etiology of liver disease should be corrected when possible, and ethanol consumption should be strongly discouraged. Abstinence from ethanol can normalize portal venous pressures in some patients with early ethanol-induced liver disease.⁶
 - Patients with early cirrhosis and diuretic-responsive ascites should not be managed by serial paracentesis; rather, medical management should be employed. In the majority of patients, ascites can be controlled with medical management.
 - In 5% to 10% of patients, ascites becomes resistant to medical treatment. The standard of care for the management of refractory ascites is therapeutic paracentesis. This can be performed as often as every 2 weeks to control symptomatic ascites.
 - Other options for managing refractory ascites include transjugular intrahepatic portosystemic shunt (TIPS) and liver transplantation. In a randomized trial of 60 patients comparing TIPS with repeated therapeutic paracentesis, the probability of survival without liver transplantation at 2 years was 58% in the TIPS patients as compared with 32% in the paracentesis patients.⁷ A smaller study of 25 patients randomized to TIPS or paracentesis demonstrated the opposite: mortality was higher in the TIPS group.⁸
 - Surgical portosystemic and peritoneovenous shunts have fallen out of favor because of the high incidence of morbidity and mortality and the development of hepatic encephalopathy.
 - For patients with tense ascites, large-volume paracentesis rapidly relieves intraabdominal pressure. A single 4- to 6-L paracentesis can be performed safely and often does not require an infusion of colloids.⁹ However, paracentesis does nothing to correct the etiology of the ascites, and ascites will recur if sodium restriction and diuretics are not instituted or fail. Referral for liver transplant evaluation should be considered for eligible patients with cirrhosis and refractory ascites.
 - Infection of ascitic fluid often occurs in cirrhotic patients. When there is no surgically correctable etiology (e.g., perforated viscus), the term *spontaneous bacterial peritonitis* is used. This diagnosis is made when there is a positive ascitic fluid culture or an ascitic fluid polymorphonuclear (PMN) cell count greater

than 250 cells/mm³ in the correct clinical scenario without any evidence for an intraabdominal, surgically correctable etiology. The infection is usually monomicrobial. Polymicrobial infection suggests secondary peritonitis. Consideration of the diagnosis mandates paracentesis and evaluation of the ascitic fluid; a clinical diagnosis without paracentesis is inadequate.

DIAGNOSTIC PERITONEAL LAVAGE: BEFORE PROCEDURE

Indications

- With the widespread use of focused abdominal sonography for trauma (FAST), the indications for diagnostic peritoneal lavage (DPL) are decreasing.
- Patients who have sustained blunt trauma and have no overt signs of acute abdominal injury or bleeding but require an evaluation to rule out intraabdominal hemorrhage or hollow viscus injury
- Patients who are not candidates for computed tomography (CT) (e.g., because of hemodynamic instability) or when FAST is unavailable or yields equivocal results

Contraindications

- The only absolute contraindication to performing a DPL is the clinical condition of the patient mandating immediate laparotomy.
- Relative contraindications include previous abdominal surgery, cirrhosis, obesity, and coagulopathy.
- In patients with pelvic fractures or pregnancy, a supraumbilical incision should be performed.

Equipment

- Local anesthetic
- Chlorhexidine prep
- Sterile towels, gloves
- 10-mL syringe
- 8F to 9F 25-cm lavage catheter
- 2-0 polypropylene suture

ANATOMY

DPL should be performed in the midline of the abdomen immediately below the umbilicus, or above the umbilicus in patients with a pelvic fracture, suspected pelvic hematoma, or pregnancy. Prior surgical incisions should be avoided if possible.

PROCEDURE

- The patient should be in the supine position. Gastric and bladder decompression tubes should be inserted to minimize the risk of injury to these organs. The periumbilical skin should be prepped and draped sterilely. Local anesthesia is injected into the site.
- DPL can be performed with an open, semiopen, or closed technique.
 - The open technique employs a midline infraumbilical abdominal incision 2 to 5 cm in length; the incision should be supraumbilical if the patient has a pelvic fracture or is pregnant. A small incision is made in the midline abdominal fascia and peritoneum. An 8F to 9F 25-cm lavage catheter with side holes is inserted under direct visualization toward the pelvis.
 - The closed method uses a Seldinger technique. A 16-gauge, 3-inch needle is inserted through a skin puncture and into the peritoneal cavity. A guide wire is passed through the needle into the peritoneal cavity. The lavage catheter is inserted over the wire.
 - The semiopen technique involves incising the skin and fascia and then using a guide wire technique for inserting the catheter into the peritoneal cavity.

- Once the catheter is placed, aspiration should be attempted with a syringe.
- If 10 mL of blood is aspirated, the DPL is considered positive, and appropriate surgical intervention should be undertaken.
- Otherwise, 1 L of crystalloid solution is infused (10 mL/kg in pediatric patients) and then retrieved by gravity and sent to the laboratory for analysis.
- In general, the DPL is considered positive in blunt-trauma patients if
 - Red blood cell (RBC) count is greater than 100,000/mm³
 - White blood cell (WBC) count is greater than 500/mm³
 - Amylase concentration is greater than 100 IU/L
- Other positive findings include the presence of bile or food particles or the drainage of lavage fluid from the bladder drainage catheter, gastric tube, or thoracostomy tube.
- The sensitivity and specificity of the test are dependent on the threshold criteria for determining a positive test result.
- If the lavage is negative but there is a high index of suspicion for intraabdominal pathology, the DPL catheter can be left in place for repeat lavage to rule out delayed hemoperitoneum or intestinal perforation.

AFTER PROCEDURE

Complications

- Infrequent
 - Bowel or vascular injury occurs in less than 1%.¹⁰
 - Bladder injury
 - Bleeding (cause for a false-positive DPL result)
 - Wound infection

OUTCOMES AND EVIDENCE

- Evaluation of the abdomen is a critical component in the assessment of injured patients. Failure to identify intraabdominal injury results in preventable morbidity and mortality in trauma patients. The physical examination for abdominal injury is often hampered by alterations of the sensorium by substances (e.g., ethanol and illicit drugs), injury to the central nervous system, or pain from other injuries. Moreover, a significant amount of blood can be present in the peritoneal cavity without obvious abdominal distention or peritoneal signs.
- DPL, CT, and ultrasonography have emerged as the main diagnostic modalities to evaluate trauma patients and currently have complementary roles. DPL was introduced by Root and colleagues in 1965 for the evaluation of abdominal trauma.¹¹
 - In the era before CT and ultrasonography, DPL was the first well-established method to identify hemoperitoneum in trauma patients.
 - DPL is primarily useful in diagnosing hemoperitoneum from blunt, solid-organ injury, but it can also be helpful for the diagnosis of hollow viscus injury.
- For *hemodynamically stable* patients with an equivocal abdominal examination, associated neurologic injury, or painful injuries, abdominal CT is recommended as the diagnostic modality of choice and has all but eliminated the need for DPL in these patients.
 - CT is also the preferred diagnostic method for determining whether nonoperative management of a solid-organ injury is appropriate.
 - Furthermore, in stable patients with a positive DPL, a follow-up abdominal CT should be considered. Thus, CT and DPL play complementary roles in evaluating stable patients following blunt abdominal trauma.
- For *hemodynamically unstable* patients, FAST and DPL are the preferred tests, with FAST rapidly gaining acceptance over DPL in many trauma centers as the preferred initial diagnostic modality.

- FAST and DPL are used to rule out hemoperitoneum as the cause of hemodynamic instability.
- In contrast to DPL, FAST can be used to identify pericardial tamponade.
- These tests can be performed expeditiously, and ongoing efforts at resuscitation and evaluation can occur simultaneously with the performance of the test.
- Since resuscitation is difficult during CT, CT is contraindicated when patients are hypotensive or hemodynamically unstable.
- DPL is also useful in certain clinical scenarios. Consider, for example, a head-injured patient needing an emergency craniotomy: DPL can be performed in the operating room at the same time as the craniotomy without interfering with the neurosurgical procedure.
- Controversy exists regarding the best way to manage blunt trauma patients with isolated evidence of free intraabdominal fluid by CT but without evidence of solid-organ injury.
 - In a review of the literature, isolated free fluid was observed in 2.8% of over 16,000 blunt trauma patients studied with CT.¹² Of these, only 27% underwent a therapeutic laparotomy, so some experts recommend serial abdominal examinations, whereas others recommend surgical exploration to rule out hollow viscous injury.
 - DPL can be useful in the evaluation of patients with suspected perforated viscus. Very early after bowel perforation, the WBC count in the lavage fluid may be low; however, within a few hours after injury, the degree of inflammation is usually sufficient to increase the WBC count in the lavage fluid to greater than 500 cells/mm³. The presence of bile, amylase, bacteria, or food particles in the lavage fluid also confirms intestinal perforation.
- The use of DPL in the evaluation of hemodynamically stable patients with penetrating abdominal wounds remains controversial.
 - A significant number of missed injuries remain undetected by this method. For example, Kelemen et al.¹³ reported a 21% false-negative rate for stable patients with abdominal gunshot wounds. Using a low RBC threshold (1000/mm³) has been described in an attempt to overcome this shortfall.¹⁴
- False-positive DPL leading to unnecessary laparotomy may occur in as many as 30% of cases.^{10,15} This problem can be reduced by using CT as a complementary test in stable patients. The false-negative rate (i.e., failure to diagnose hemoperitoneum) is low. However, DPL is unable to detect retroperitoneal injuries (CT is the preferred test to detect retroperitoneal injuries for the stable patient) and is insensitive for detecting early hollow viscous and diaphragmatic injuries.
- One of the major problems with DPL is that the test is too sensitive. Only about 30 mL of the blood in the peritoneal cavity is necessary to produce a positive DPL. In this era of selective management of solid-organ injuries, a significant number of nontherapeutic laparotomies would be performed on the basis of these DPL results unless the diagnostic evaluation includes other modalities as well.
- Proponents of the open technique argue that it is safer, whereas proponents of the closed and semiopen methods argue that these approaches are more expeditious and can be safely performed by appropriately trained individuals.
- A large meta-analysis that aggregated the results from 1126 patient trials showed that the incidence of major complications is not different for the diverse DPL techniques.¹⁶
- Failure to properly place the catheter and technical difficulties were more likely to occur with the closed method, whereas the procedure time was shorter with the open method (17.8 vs. 26.8 minutes, respectively).
- Sensitivity, specificity, and accuracy were not different between the various methods of catheter insertion.

■ BEFORE PROCEDURE

Indications

- Pleural effusion is not explained by the clinical presentation
- Massive pleural effusion with impending respiratory failure
- Suspected pleural space infection
- Suspected complication of pneumonia (empyema)
- Suspected hemothorax

Contraindications

- Absolute
 - Lack of expertise
 - Severe uncorrectable coagulopathy (platelet count < 25,000 cells/ μ L; international normalized ratio [INR] > 2.0)
 - Azotemia (creatinine > 6 mg/dL)
 - Uncooperative patient
- Relative
 - Operator-dependent and of technical nature
 - Lack of image guidance to determine the safety of the puncture site

Equipment

- Diagnostic thoracentesis
 - Iodophor- and chlorhexidine-containing antiseptic
 - 10- and 30-mL sterile syringes
 - 21-gauge needle
 - 21-gauge spinal needle may be needed for obese patients
 - 1% lidocaine for use as local anesthetic
- Therapeutic thoracentesis
 - Commercially available catheter-over-needle system

■ ANATOMY

The pleura is a serous membrane that covers the lung parenchyma, mediastinum, diaphragm, and rib cage. The pleura is divided into the visceral and parietal pleura. The visceral pleura covers the lung parenchyma, as well as the interlobar fissures. The parietal pleura lines the inside of the chest wall and the diaphragm. As pleural fluid forms, separation of the visceral and parietal pleural occurs, creating a space for a needle to be placed safely. Free-flowing pleural fluid will collect through gravitational effects in dependent areas. Thus, if a patient is sitting upright, pleural fluid will collect along the diaphragm and the costophrenic and cardiophrenic angles. In contrast, in a supine patient, pleural fluid will collect along the posterior aspects of the lung.

The parietal pleural receives its blood supply from the systemic capillaries of the intercostal arteries supplying the costal pleura, whereas the mediastinal pleura is supplied by the pericardiophrenic artery. The diaphragmatic pleura is supplied by the superior phrenic and musculophrenic arteries. The bronchial arteries likely supply the visceral pleura. The intercostal artery, vein, and nerve travel below the ribs. It is important to understand that the neurovascular bundle is not protected by the phalange of the rib within the first 8 to 10 cm from the origin of the vessels and nerves from the spine. Performing a

thoracentesis near the spine increases the risk of intercostal artery laceration and hemothorax.

■ PROCEDURE

See Video E11-1.

- Obtain informed consent.
- Place patient in a sitting position if hemodynamically stable, or move the patient to the edge of the bed, with the head of the bed elevated to a 30- to 45-degree angle.
- Perform thoracic ultrasonography, and mark the puncture site.
- The upper margin of the rib immediately below the access area should be defined by palpation (may be impossible with obesity).
- The area should be disinfected with an iodophor- or chlorhexidine-containing antiseptic.
- Use 1% lidocaine without epinephrine for local anesthesia.
- Perform the procedure under sterile conditions at this point.
- Inject lidocaine subcutaneously into the periosteum of the rib and the parietal pleura, ensuring that the upper margin of the rib is identified and anesthetized.
- The upper margin of the rib should be identified with a 21-gauge needle before placing a thoracentesis catheter for a therapeutic procedure.
- Accessing the pleural space over the upper margin of the rib (should be identified) places the needle at a greater distance from the intercostal vessels and nerves.
- Always maintain the needle angle perpendicular to the patient.
- Once the pleural fluid is aspirated, retract the needle outside the pleural space.
- Place a 30- to 60-mL syringe onto the needle, and advance into the pleural space to collect the specimen.
- If therapeutic thoracentesis is desired, withdraw the needle after the pleural fluid is clearly aspirated.
- If fluid cannot be obtained with a small-gauge needle, no attempts at placing a thoracentesis catheter should be made.
- Insert the catheter-over-needle system under continuous application of suction until the pleural fluid is aspirated.
- Once the pleural fluid is obtained, advance the catheter system another 1 cm to place the catheter with its maximum diameter in the pleural space.
- Without advancing the needle, strip the catheter into the pleural space, and remove the needle.
- To prevent air entry into the pleural space, turn the thoracentesis stopcock off as related to the patient.
- Finally, connect the drainage tubing and collection bag to the thoracentesis catheter.
- To prevent the development of excessively negative pleural pressures in ventilated patients, draining large amounts of pleural fluid is not recommended unless pleural manometry is performed.

■ AFTER PROCEDURE

Postprocedure Care

- A postprocedure chest radiograph should be performed on all ventilated patients.

- Monitor for signs of tension pneumothorax and hemothorax
 - Hypotension
 - Worsening lung compliance in ventilated patients
 - Tube thoracostomy is required for all patients who develop a pneumothorax on mechanical ventilation.

Complications

- Common
 - A cough due to lung reinflation
 - Anterior chest pain in the setting of an unexpandable lung
 - Pain at the puncture site
 - Seroma or hematoma at the puncture site
 - Pneumothorax (up to 30% for non-image-guided procedures)
- Infrequent
 - Pneumothorax with image guidance reported between 0% and 3%
 - Inadvertent puncture of subdiaphragmatic structures (e.g., liver and spleen)

- Hemothorax
- Serious, rare complications
 - Pneumothorax
 - Tension pneumothorax
 - Intercostal artery laceration
 - Hemothorax
 - Reexpansion pulmonary edema
 - Hypotension

OUTCOMES AND EVIDENCE

- Feasibility and safety of ultrasound-guided thoracentesis in mechanically ventilated patients are strongly supported by the literature.
- Clinically directed thoracentesis should not be performed in mechanically ventilated patients.
- Bedside ultrasonography is the preferred modality for diagnosis of pleural effusion in the critically ill patient.

BEFORE PROCEDURE

Indications

- Most commonly undertaken to treat one of the following conditions
 - Pneumothorax
 - Pleural fluid collection
 - Hemothorax
 - Simple effusion
 - Empyema
- Can be both a diagnostic and a therapeutic maneuver

Contraindications

- In an emergent situation (i.e., tension pneumothorax), there are no contraindications.
- In a nonurgent situation, caution should be exercised in the presence of
 - Known or suspected adhesions
 - Prior chest surgery or trauma
 - History of pleural space infection
 - Intrinsic parenchymal disease
 - Complex, loculated air or fluid collection(s)
 - Typically noted on imaging studies
- In situations where insertion is not emergent and is anticipated to be difficult, consideration to placement by a skilled operator (surgeon) or under image guidance (computed tomography [CT], ultrasound) is recommended.

Equipment

- Chest tube of appropriate size and configuration (Fig. E12-1)
 - In general, larger tubes are required to drain blood, pus, or viscous fluid, and smaller tubes (i.e., pigtail catheter) may suffice for a simple effusion or pneumothorax.
 - Sizes range from 20F to 40F for adults and 6F to 26F for pediatric patients.
 - Straight tubes most commonly placed in the emergency department or intensive care unit.
 - Right-angled tubes are available but typically are placed by surgeons in the operating room.
- Commercially available collection system (Fig. E12-2)
 - Includes the following components
 - Plastic connector of at least 0.25-inch diameter to connect the chest tube to the accessory tubing (a Y connector may be used in the case of multiple chest tubes, but caution is advised because these are prone to occlusion and subsequent drainage failure).
 - Accessory tubing (generally 0.5 inch in diameter and 6 feet long)
 - Drainage system (composed of a trap, water seal, and manometer compartments)
- Wall vacuum source with connection tubing
- Prepackaged chest tray
 - At a minimum, should contain a scalpel and a clamp (large Kelly clamp or hemostat)

- Skin antiseptic
- Sterile drapes
- Sterile gown and gloves, mask, and cap
- Local anesthetic
- Intravenous narcotic and/or sedative
- Suture material (commonly 0 silk)
- Gauze
- Tape

ANATOMY

Entry into the pleural space should generally be gained via a location based on ease of access, safety, and avoidance of complications. The American College of Surgeons Committee on Trauma recommends drain insertion between the anterior and posterior axillary lines at a level with or just above the fifth intercostal space (nipple level). In this location, the chest wall is thinnest, and the operator can avoid the pectoralis major muscle and breast parenchyma (anteriorly), the latissimus dorsi muscle (posteriorly), the axillary vessels/brachial plexus (superiorly), and the diaphragm/intraabdominal contents (inferiorly). Within the intercostal space, coursing along the inferior surface of each rib is the neurovascular bundle. Insertion of the tube over the superior aspect of the rib is recommended so that injury to these structures can be avoided (Fig. E12-3). From superficial to deep, one will first encounter skin, followed by a variable amount of subcutaneous tissue, the superior surface of the rib, the intercostal space with its musculature, and finally the parietal pleura. The pulmonary parenchyma and mediastinal structures are deep to the parietal pleura, so it is important to avoid overzealous insertion of the chest tube. In some instances (e.g., a loculated collection), specialized placement may be required, and the assistance of a surgeon or insertion under image guidance is encouraged.

PROCEDURE

See Video E12-1.

- If nonemergent, perform a “time-out” to verify the indication(s), review the relevant imaging and coagulation studies, and confirm the correct patient and laterality.
 - A procedural checklist may be helpful and has been shown to reduce errors and decrease complications.
- Obtain necessary equipment (see earlier), and fill the water seal compartment of the collection system with water.
- Position as follows
 - Supine or slight elevation of the head of the bed
 - Ipsilateral arm behind the head or abducted
 - Bed at comfortable height for the operator
 - Ensure adequate lighting.
- Practice aseptic technique, and apply Universal Precautions.
- Prep the area broadly with skin antiseptic.
- Drape widely such that anatomic landmarks (e.g., the nipple) are visible.
- Plan the skin incision to overlie the rib just inferior to the chosen intercostal space (i.e., if entering the fifth interspace, place the incision along the superior aspect of the sixth rib).
- Consider premedication with a narcotic or anxiolytic.

FIGURE E12-1 ■ Standard chest tube (*top*) with trocar (*middle*) and angled chest tube (*bottom*) without trocar.

FIGURE E12-2 ■ Modern chest drainage system. **A**, Accessory tubing to wall suction. **B**, Accessory tubing to chest tube/patient. **C**, Suction control. **D**, Float indicating suction is operative. **E**, Water seal chamber. **F**, Collection chamber. **G**, Air leak meter.

FIGURE E12-3 ■ Use of Kelly clamp to enter pleural space.

- Inject local anesthetic (apply aspiration at all times)
 - First anesthetize the skin.
 - Then angle the needle slightly cephalad to anesthetize the periosteum of the rib and the deeper tissues.
 - Several passes may be required to cover an area 1 to 2 cm in diameter.
 - If air or fluid is aspirated, retract the needle while aspirating it until it ceases and then inject additional local to anesthetize the parietal pleura.
- Make an incision large enough to accommodate the operator's index finger and chest tube at the same time.
- Bluntly dissect (with index finger and/or Kelly clamp) along an oblique path angled superiorly to the chosen intercostal space, with care taken to remain on the superior border of the rib (see Fig. E12-3).
- If the patient is on a ventilator, hold respirations temporarily.
- Gently enter the pleural space with the tip of the clamp.
 - Avoid excessive clamp insertion to minimize injury to deeper structures.
 - Typically will feel a pop and get return of air and/or fluid
- Open the clamp slightly to sufficiently enlarge the opening into the pleural space.
- Insert index finger to confirm entry into the pleural space.
 - Should be able to palpate parietal pleura and, at times, the lung
 - Note the presence of any adhesions (seen in up to 15% of cases).
- We recommend discarding the chest tube trocar and grasping the end of the tube with the Kelly clamp to facilitate safer insertion.
- Insert index finger alongside the chest tube, and guide the tube into the pleural space away from the lung parenchyma.
 - Though it is recommended to direct the tube anteroapically for a pneumothorax and posterobasally for fluid, exact location within the pleural space is probably not important in most cases.
 - Ensure that the last drainage hole is well within the pleural space.
- Connect the tube immediately to the collecting system.
- If suction is desired, adjust the wall vacuum source to provide slow, consistent bubbling.
 - Typically, the collection system is set initially to -20 cm H_2O suction.
- Secure the tube to the skin at the exit site with sutures (avoid a purse-string stitch).
- Cover the wound with dry gauze and tape.
- Obtain a chest x-ray to document proper placement, evaluate expansion of the lung, and assess for residual pleural fluid or air.

AFTER PROCEDURE

Postprocedure Care

- Daily assessment
 - System must remain upright and should be kept below chest level.
 - The accessory tubing should be in a straight or coiled position and not kinked.
 - Be certain the water level in the system is maintained.
 - If suction is being used, verify the proper setting and confirm that it is functional (the float should be visible in the window).
 - Note the amount of drainage, presence of bubbling, and respiratory variation.
- Troubleshooting
 - Observation of synchronous water seal and motion with respiration suggests the tube is still functioning in the pleural space and that all connections are tight.
 - If the tube is not functioning and occlusion of the drainage holes is suspected
 - Disconnect and flush with normal saline
 - Consider fibrinolytics (particularly if a parapneumonic effusion is present)

- If an air leak within the system is suspected
 - Sequentially clamp the accessory tubing with distal suction applied. The leak will cease when a clamp is placed proximal to the site, and the problem can then be addressed.
 - If the accessory tubing or the connections are not the problem, check the insertion site. If the skin incision is too large, the leak may be audible and can readily be addressed with an additional stitch. Also, be certain the last drainage hole has not migrated out of the pleural space.
 - If neither of the above identifies the problem, a major airway injury or bronchopleural fistula may be to blame.
- Removal
 - Should be performed once the indication for tube thoracostomy has resolved
 - Will vary somewhat according to the patient population and the indication for insertion
 - For simple pneumothorax, hemothorax, or pleural effusion, we recommend
 - Placement of the tube on -20 cm H_2O suction initially to facilitate lung reexpansion and/or evacuation of fluid.
 - Suction may not be required in some patient populations (i.e., those without underlying lung disease or who do not require mechanical ventilation).
 - Continue suction until the lung is reexpanded and there is no air leak. Then convert to water seal.
 - Obtain a radiograph on water seal to confirm lung expansion.
 - Remove when drainage is negligible (<150 - 200 mL per day).
 - For empyema, the infectious process must be resolved, there should be no residual empyema cavity on imaging studies, and drainage must be scant prior to removal.
 - It is common for empyema tubes to remain in place for weeks.
 - In lung resection patients, management is more complex because the routine use of suction may potentiate air leaks. We recommend consultation with the patient's surgeon regarding management of the tube(s).
 - The timing of chest tube removal relative to the respiratory cycle (i.e., end inspiration or end expiration) does not appear to be important, even in ventilator-dependent patients.
 - Although routine chest radiography after removal is not a universal practice, we recommend obtaining one within 4 hours of removal to confirm lung expansion.
 - Routine clamping of chest tubes should generally be avoided.
- Clinically more important that the tube reside in the pleural space rather than a specific location relative to the chest wall or lung parenchyma.
- Infectious
 - Insertion site (wound) infection
 - Pleural space infection (empyema) rates vary from 1% to 11%.
- Unresolved pneumothorax
- Persistent pleural fluid collection
- Infrequent
 - Injury to the lung
 - May manifest as hemothorax, persistent air leak, residual pneumothorax, or subcutaneous emphysema
 - Injury to the intercostal vessels
 - May manifest as hemothorax and occasionally requires surgery to achieve hemostasis
 - Chylothorax
 - Long thoracic nerve injury (winging of the scapula)
 - Intercostal neuralgia
 - Horner's syndrome
 - Phrenic nerve palsy
- Serious rare complications
 - Reexpansion pulmonary edema
 - Manifests as dyspnea (in the absence of lung collapse) following drainage of a large pneumothorax or hemothorax
 - Ipsilateral edema seen on chest radiograph
 - Treatment is supportive
 - Some recommend slow removal of large effusions (<1 L in the first 30 minutes) to minimize the risk.
 - Esophageal rupture
 - Perforation of the heart or great vessels
 - Laceration of the subclavian vessels
 - Injury to the diaphragm and/or upper abdominal structures (liver, spleen, stomach, colon)
 - Puncture of silicone breast implants (intrathoracic silicosis)

OUTCOMES AND EVIDENCE

- Few aspects of chest tube management have been subjected to rigorous study or are standardized.
- Patient outcomes following tube thoracostomy are related to their underlying condition(s).
 - Deaths due to the procedure itself are infrequent.
- No clear consensus exists regarding the role of prophylactic antibiotics for tube thoracostomy, but they may be of some benefit.
- Recent meta-analysis of studies performed in trauma patients revealed a reduction in the risk of posttraumatic empyema and pneumonia.
- If one elects to administer antibiotics, coverage against *Staphylococcus* should be chosen.

Complications

- Reported to be as low as 2% and as high as 30%
- Improper insertion technique, operator inexperience, and forceful use of sharp trocars are avoidable errors that account for many of the complications.
- Common
 - Malpositioning
 - Generally around 3%, though a recent study of critically ill patients who underwent CT following tube thoracostomy reported an incidence of 30%.

■ PREPROCEDURE

Indications

- Diagnostic uses
 - To assess the patency and anatomy of the upper airway
 - To evaluate problems associated with endotracheal tubes and airway stents, such as tracheal damage, device malposition, or airway obstruction
 - To investigate lung abnormalities of unclear etiology on the chest x-ray
 - To investigate unexplained hemoptysis, cough, and localized wheeze or stridor
 - To obtain lower respiratory tract specimens by bronchoalveolar lavage (BAL) or protected specimen brushing (PSB) for cytologic or microbiologic analyses
 - To investigate the etiology of positive sputum cytology results
 - To determine the location and extent of respiratory tract injury after toxic inhalation or aspiration of gastric contents
 - To evaluate the airways for suspected tracheobronchial injury after thoracic trauma
 - To evaluate a suspected tracheoesophageal fistula
 - To perform endobronchial or transbronchial lung biopsies (TBLBs) and transbronchial needle aspirations (TBNAs) for histologic, cytologic, or microbiologic analyses
- Therapeutic uses
 - To remove retained secretions or mucous plugs not mobilized by physiotherapy
 - To retrieve foreign bodies (Videos E13-5 and E13-6)
 - To perform difficult tracheal intubations
 - To aid in performing percutaneous tracheostomies (Video E13-4)
 - To perform selective intubation of the main stem bronchus
 - To place airway stents
 - To perform airway balloon dilatation for the treatment of tracheobronchial stenosis
 - To remove abnormal endoluminal tissue from the trachea or bronchi through the use of forceps or laser techniques

Contraindications

- Absolute contraindications
 - Absence of consent from the patient unless a medical emergency warrants the procedure
 - Lack of trained personnel to perform or directly supervise the procedure
 - Lack of adequate personnel and facilities to manage possible life-threatening emergencies
 - Inability to adequately oxygenate the patient
 - Inability to normalize the platelet count and coagulation if biopsy is anticipated
 - Unstable hemodynamic status
 - Active uncontrolled bronchospasm
- Relative contraindications
 - Lack of patient cooperation
 - Unstable angina or recent myocardial infarction (within 6 weeks)

- Hypercapnia
- Brain injury (risk for increased intracranial pressure)
- Severe pulmonary hypertension and uremia (increased risk for serious hemorrhage following biopsy)

Equipment

- Fiberoptic bronchoscope, comprised of a few components that are incorporated into a functional unit (see Figs. E13-1 and E13-2)
 - Control handle: it contains
 - Body that fits into the hand
 - Eyepiece, to which video or photographic devices may be attached; just under the lens, a diopter adjustment ring is used to focus and adjust the eyepiece to fit each individual's eyesight; in some bronchoscopes, the top of the endoscopic view is marked by an indent or black triangle to assist in orientation
 - Bending lever; located on the back of the handle and used to activate the up and down movement of the last 2 to 3 cm of the insertion cord
 - Suction control valve
 - Suction connector
 - Access port to the working channel
 - Insertion cord: it is the flexible bronchoscopic element that hangs from the control handle and is introduced into the airways; within it are the viewing bundle, one to three light bundles, the working channel, and two wires to control the distal end of the scope.
 - Universal cord: it arises from the side of the control handle and transmits the light from the light source to the endoscope and then down to the insertion cord to illuminate the field of view. The light source is a metal box to which the universal cord attaches. In some types of bronchoscopes (portable scopes) the universal cord is not needed, as the light source is built into the control handle of the instrument and power is provided by a battery system. Modern digital flexible endoscopic systems use a charge-coupled device chip placed at the end of the scope to relay digitized information to the monitor via a processor. The venting connector is a component of the bronchoscope usually located on the universal cord. The ethylene oxide sterilization venting cap and leakage tester are attached to this connector. The ethylene oxide cap must be installed when the endoscope is subjected to gas sterilization and during transportation by air and must be removed before immersion or when the instrument is in use.
- Ancillary technical materials
 - Venous access equipment
 - Oxygen and related delivery equipment
 - Wall or portable vacuum systems and related suction supplies
 - Laser equipment, if applicable
 - Bite block, to be used in transoral procedures in awake patients
 - Sterile gauze, for clearing the tip of the bronchoscope during the procedure
 - Water-soluble lubricant
 - Antifogging systems, including warm water (max 60°C), weak soap solutions, and commercially available antifogging solutions;

when fogging occurs during the procedure, bringing the tip of the endoscope into contact with the mucosal surface may eliminate lens fogging

- Microbiology and cytology brushes, flexible forceps, retrieval valves, transbronchial aspiration needles, fixatives
- Specimen-collection traps, syringes for medication delivery, normal saline solution for bronchoalveolar lavage
- Laryngoscope
- Endotracheal tubes in various sizes
- Oral intubating airway that provides an open air space in the oropharynx and protects the endoscope from being bitten by the patient; it is useful if the oral route is chosen in patients under general anesthesia
- Endoscopy masks to assist fiberoptic intubation in patients being ventilated by a face mask provided with a rubber diaphragm that permits the passage of either the endoscope or the tracheal tube into the airways and prevents air leakage
- Endotracheal tube introducers of various sizes
- Cricothyroidotomy kit
- Laryngeal mask airway or other extraglottic devices of various sizes for ventilator support in emergency situations; laryngeal mask airway may also be used to aid the passage of the bronchoscope into the trachea
- An adapter for the insertion of the bronchoscope into the airways while preventing loss of the respiratory gases and maintaining ventilation and positive end-expiratory pressure throughout the procedure during either invasive or noninvasive ventilation (NIV)
- Self-inflating or anesthesia bag attached to a face mask by a T-adapter, for bag-mask ventilation in nonintubated, sedated patients undergoing bronchoscopy
- Resuscitation equipment
- Medications
 - Lidocaine for topical anesthesia; the minimum amount of lidocaine necessary should be used when installing through the endoscope; the total dose of lidocaine should be limited to

8.2 mg/kg in adults; great care must be given when administering lidocaine to patients with liver or cardiac failure

- Sedative agents (e.g., benzodiazepine and propofol)
- Synthetic narcotics (e.g., fentanyl or remifentanyl) to provide sedation and analgesia and to suppress the cough reflex
- Benzodiazepine and/or narcotic antagonists
- Epinephrine (usually 1 : 10,000 dilution), for bleeding control
- Nasal decongestants
- Emergency and resuscitation drugs
- Monitoring devices
 - Pulse oximeter
 - Continuous electrocardiogram
 - Continuous intraarterial blood pressure or intermittent cuff blood pressure measurement at least every 5 minutes
 - Intracranial pressure, essential in patients with serious brain injury
 - End-tidal carbon dioxide, useful in patients with brain injuries
 - Respiratory function monitoring of patients under mechanical ventilation, for ventilation parameters such as exhaled tidal volume and peak inspiratory pressure
 - Chest x-ray 1 hour after transbronchial biopsy to exclude pneumothorax
- Cleaning and sterilization equipment
 - Dedicated room for cleaning and manual or automated sterilization; automated washer disinfectors are recommended to minimize staff contact with disinfectant and their fumes
 - Soft nonabrasive cleaning cloth to gently wipe the external surfaces and components of the endoscope immediately after use
 - Water or neutral detergent solution to irrigate all accessible channels of the endoscope at the end of the procedure
 - Leak testing system
 - Cleaning brushes and neutral detergent solution for a thorough cleaning of the internal and external surfaces of the endoscope: cleaning brushes are passed through the working channel access port, the suction port opening, and the suction connector. They

FIGURE E13-1 ■ Fiberoptic bronchoscopy in a patient under mechanical ventilation. Note how the operator uses her right hand to hold the handle of the instrument, with her thumb over the bending lever and her index finger over the suction control valve. B, body; BL, bending lever; CA, camera attachment; CH, control handle; E, eyepiece; IC, insertion cord; RC, respiratory circuit; SC, suction connector; SCV, suction control valve; UC, universal cord; WCAP, working channel access port.

FIGURE E13-2 ■ Fiberoptic bronchoscopy in a patient under mechanical ventilation. The operator uses a recent model, battery-driven bronchoscope incorporating video camera, light source, and recording unit. The camera body of this bronchoscope can be rotated to the right and the left side by 90 degrees to either side, and the liquid crystal display panel can be tilted from 0 to 120 degrees. CB, camera body; IC, insertion cord; RC, respiratory circuit; SCV, suction control valve; WCAP, working channel access port.

are also used carefully to clean the distal end of the instrument; the brush head should be cleaned each time it emerges from the endoscope

- Protease enzymatic agent for cleaning and the removal of blood and protein residues
- High-level disinfection or sterilization agents (e.g., peracetic acid, glutaraldehyde, or ethylene oxide)
- Sterile water for rinsing the endoscope
- 70% ethyl or isopropyl alcohol to flush the external surfaces and inner channels of the endoscope, when the quality of the rinse water is in doubt or to assist in the drying process
- Cupboard to hang the endoscope

ANATOMY

- See Video E13-1 Trachea
- The trachea is a tube that passes from the larynx to the level of the fourth/fifth thoracic vertebra where it bifurcates into the two main bronchi (i.e., the left and the right) at the anatomic point known as the *carina*. The trachea has an inner diameter of about 21-27 mm and a length of about 10-16 cm. About 15-20 incomplete C-shaped cartilaginous rings reinforce the anterior and lateral sides of the trachea and main bronchi. The posterior wall, or membranous trachea, is free of cartilage and contains bundles of muscle fibers that are inserted into the posterior ends of the cartilage plates.
- Bronchi
 - The right main bronchus is wider, shorter, and more vertical than the left main bronchus. The cartilage and mucous membrane of the main bronchi are similar to those of the trachea. At the level where the main bronchi enter the lungs, the membranous region disappears, and the cartilage plates are no longer C-shaped but are smaller, more irregular, and arranged to surround the circumference of the airway. At this level, the muscle coat no longer inserts into the cartilage but forms a separate layer of interlacing bundles. Consequently, the airway lumen can be occluded by the contraction of the muscle.
 - The right main bronchus subdivides into three lobar bronchi, while the left main bronchus divides into two, although the lingula of the left lung is analogous to the right middle lobe. The lobar bronchi divide into segmental bronchi, each of which supplies a bronchopulmonary segment. The bronchopulmonary segments are the topographic units of the lung, and they are used to identify regions of the lung either radiologically or surgically. There are ten bronchopulmonary segments per lung, but, due to anatomic development, some of the segments in the left lung fuse, giving rise to eight segments. For counting orders or generations of airways, the main bronchi are usually counted as the first generation, the lobar bronchi as the second generation, and so on. Generally, in adult subjects, a bronchoscope with an outer diameter of 5 mm cannot be advanced farther than the fourth/fifth-order bronchi.
- Bronchioles
 - As the branching continues through the bronchial tree, the amount of hyaline cartilage in the walls decreases until it is absent in the bronchioles, which lie distal to the bronchi, beyond the last plate of cartilage. When any airway is pursued to its limit, the terminal bronchiole is reached. Each terminal bronchiole then gives rise to several respiratory bronchioles, which lead to the alveolar ducts and sacs. The alveolus is the basic anatomic unit of gas exchange in the lung.
- Nomenclature of peripheral bronchi
 - The nomenclature commonly used for the bronchial anatomy is that of Jackson and Huber. There are ten segments in the right lung and eight in the left. Subdivisions of the bronchial tree correspond to the anatomic segments and are named accordingly.

The right main bronchus gives rise to three lobar bronchi: upper, middle, and lower. The portion of the right main bronchus between the upper lobe bronchus and the origin of the middle and inferior lobe bronchi is known as the lower part of the right main bronchus, or bronchus intermedius. The right upper lobe bronchus is subdivided into three segmental bronchi: the apical, posterior, and anterior. The right middle lobe bronchus branches into two segmental bronchi: the lateral and medial. The right lower lobe bronchus gives rise to five segmental bronchi: the superior segmental bronchus, posteriorly directed and just below the orifice of the middle lobe bronchus, and more distally, four basal segmental bronchi: the medial, anterior, lateral, and posterior; occasionally, the medial basal bronchus is partially separated from the other basal segments by an extra fissure.

The left main bronchus subdivides into two lobar bronchi: the upper and lower. The left upper lobe bronchus subdivides into a superior division bronchus and a lingular division bronchus. The superior division has two segmental bronchi: the apical-posterior and anterior. The lingular division has two segmental bronchi: the superior and inferior. The anatomy of the left lower lobe bronchus is similar to that of the right lower lobe bronchus, except that there are usually only three basal segmental bronchi on the left: the anteromedial, lateral, and posterior; additionally, the left lower lobe bronchus has a greater distance between its superior segment and its basal pyramid bronchi, compared to the right side.

With the advent of fiberoptic bronchoscopy, Dr. Shigeto Ikeda introduced additional nomenclature for the fourth, fifth, and sixth divisions. According to this nomenclature, the segmental bronchi are numbered from 1 to 10 on each side and are identified with the capital letter "B" for bronchus and prefixed by the capital letter "R" for right or "L" for the left. This way, LB6 identifies the superior segmental bronchus of the left lower lobe. Subsegmental or fourth-order bronchi are designated by the lowercase letter "a" for posterior and "b" for anterior; the letter "c" may be used for additional bronchi. Fifth-order bronchi are identified by the Roman numerals "i" (posterior) and "ii" (anterior). Finally, "α" and "β" are used for sixth-order bronchi.

- Variations in the bronchial anatomy are not infrequent.
- Key bronchoscopic anatomic features as viewed by an operator positioned at the head end of a supine patient
 - Right lung. The orifice of the bronchus to the right upper lobe is in the 3 o'clock position, and its distance from the carina is quite variable. The arrangement of the three segmental bronchi of the right upper lobe bronchus is nearly symmetric. Just beyond the lower section of the right main bronchus, or bronchus intermedius, the typical anatomic configuration consists of the orifice of the middle lobe bronchus, anteriorly directed, in the 12-2 o'clock position; the orifice of the bronchus to the superior segment of the lower lobe, at the same level but in the 6-7 o'clock position; and, directly in front, the basal segmental bronchi of the right lower lobe.
 - Left lung. After entering the left main bronchus, the orifices of the upper and lower lobe bronchi generally lie in the top left and bottom right, respectively, of the bronchoscopic image. Within the orifice of the left upper lobe bronchus, the lingular division bronchus lies to the right of the superior division bronchus. Inside the entrance of the left lower lobe bronchus, the orifice of the superior segmental bronchus is in the 6-7 o'clock position, just as in the right lung.

PROCEDURE

- Define the indication for fiberoptic bronchoscopy.
- Choose the size of the bronchoscope according to the indication of procedure, the patient size, and the size of the endotracheal tube; a

large bronchoscope with a wide working channel provides excellent suction performance and permits the passage of large bronchoscopic tools. In adult patients with tracheal intubation, an outer diameter of the bronchoscope at least 1.5 mm narrower than the lumen of the endotracheal tube can prevent excessive increases in airflow resistance and decreases in the tidal volume.

- Assure the bronchoscope is in proper working order.
- Check any cameras and/or video equipment that may be used.
- Assess the patient's medical, physiologic, and psychologic status.
- Reassure the patient, if conscious.
- Prescribe appropriate premedication, if needed.
- Establish intravenous access.
- Connect the bronchoscope to the light source when it is present, turn on the light, adjust the focus (e.g., by looking at written material until a clear view is obtained), and obtain the white balance.
- Connect the suction catheter to the suction connector.
- Place the distal end of the insertion cord of the bronchoscope into warm water.
- Apply or check the monitoring.
- Place the patient in a supine, semirecumbent, or even sitting position, depending on the type of procedure.
- Start topical anesthesia, general anesthesia, or intravenous sedation, based on the needs of the patient.
- Stand behind or to the left or right side of the patient. If you stand to the side, you can approach the patient either from behind or the front; in the latter situation, once the bronchoscope has passed into the pharynx, the superior part of the endoscopic view will correspond to the inferior region of the patient.
- Lubricate the bronchoscope.
- Handling the bronchoscope. Right-handed users will find it easier to hold the handle of the instrument with their right hand, with the index finger over the suction valve and the thumb over the bending lever, and to use their left hand to hold the insertion cord. The black cursor in the viewfinder, when present, describes the plane of movement of the tip of the endoscope.
- The bronchoscopic procedure requires only three movements: (1) flexion of the tip of the bronchoscope along the plane of the cursor; (2) rotation of the entire endoscope to the left or right; and (3) the advancement or withdrawal of the instrument. The goal is to keep the point of interest (e.g., vocal cords, bronchial orifice, etc.) in the center of the field. When the bending lever is depressed, the tip rises, whereas when the lever is elevated, the tip points downward. The insertion cord should be kept as straight as possible to either prevent accidental damage to the bronchoscope or improve the control over the tip of the instrument. To look right, the tip of the bronchoscope may be turned upward while the control handle is twisted clockwise. Alternatively, the insertion cord may be rotated anticlockwise with the tip turned downward. To look left, the insertion cord is rotated clockwise or anticlockwise with the tip deflected downward or upward, respectively. The operator will decide which maneuvers to perform depending on the ease of obtaining the desired movements.
- The insertion cord should be able to rotate throughout its length when the handle is rotated axially, to avoid distortion of the image orientation. This orientation distortion resulting from the axial rotation usually occurs when the distal end of the bronchoscope is blocked by the air-tight rubber seal at the entrance of the endotracheal tube or even by the inside walls of the tube. In these circumstances, the tip of the bronchoscope fails to rotate synchronously with the proximal end of the instrument.
- When a camera attachment is used with the bronchoscope, the camera position relative to the bronchoscope needs to be calibrated by rotating the bronchoscope camera system until a certain movement inside the patient's airway corresponds with the proper motion on the monitor.
- The bronchoscope may be inserted into the airway through the nose or the mouth in spontaneously breathing patients or through the endotracheal tube in intubated patients. During NIV, the bronchoscope is passed through the NIV interface (Videos E13-2 and E13-3).
- The application of NIV during bronchoscopy may be useful either in at-risk hypoxemic patients who are initially breathing spontaneously and who start NIV to assist bronchoscopy or in patients who are already receiving NIV and scheduled to undergo bronchoscopy during NIV. When NIV is administered through a facial mask, a T-adaptor with a sealed connector is attached to the mask for insertion of the bronchoscope through the nose or the mouth.
- Fiberoptic intubation. The endoscope may be passed transnasally or transorally through the vocal cords into the trachea. Then the endotracheal tube is slipped over the instrument.
- Sampling techniques. Samples from the lower airways are commonly obtained by BAL, PSB, TBLB, and TBNA. When BAL or PSB is performed, the sampling area is selected based on the location of the new or progressive infiltrate on a chest x-ray or the segment visualized during bronchoscopy as having purulent secretions. Data are lacking for the optimal sampling site in patients with diffuse lung infiltrates.
- BAL. The tip of the bronchoscope is wedged as far as possible into a distal airway (generally a fourth- or fifth-order bronchus), and a sterile saline solution is instilled through the bronchoscope and then aspirated into a sterile trap. Aliquots of 20 to 60 mL are injected and aspirated back after each instillation. The total amount of fluid used to perform BAL ranges from 140 to 240 mL. In the supine patient, BAL fluid recovery is best from the right middle lobe or lingula. At least 5 mL of retrieved fluid is needed for adequate microbiologic analysis. The first aliquot of aspirated fluid is likely to contain a large amount of material from the proximal airway and must be analyzed separately from the rest. The recovery of more than 5% squamous epithelial cells in the BAL specimen indicates proximal tracheobronchial contamination. Since lidocaine has bacteriostatic properties, the use of this local anesthetic could alter the microbiologic results.
- PSB. This technique is performed using a retractable brush within a double-sheathed catheter device with a distal dissolvable plug occluding the outer catheter. First, the tip of the bronchoscope is positioned close to the sampling area. Next, the catheter is inserted through the working channel and advanced 1 to 3 cm beyond the distal end of the bronchoscope to avoid the collection of pooled secretions around the distal tip of the instrument. The inner catheter containing the brush is advanced to eject the distal plug into a large airway, and the brush is advanced under direct vision into the desired subsegment. Once the sample is obtained, the brush is retracted into the catheter, which is then withdrawn and removed from the bronchoscope. The brush is then advanced beyond the catheter, cut with sterile scissors, and placed into 1 mL of transport medium to avoid drying.
- TBLB. Histologic samples of the bronchial mucosa, bronchial wall, lung parenchyma, and alveoli may be obtained using TBLB. In diffuse lung disease, the biopsy specimen should be taken from a peripheral airway, preferably the lower lobe. In this way, the danger of significant bleeding may be reduced, owing to the smaller caliber of the distal bronchial vessels. The number of biopsies needed for TBLB is not standardized. However, seven to eight biopsy specimens have been proposed for localized lung lesions, whereas five TBLB samples from one lung seem to ensure a high diagnostic yield for most diffuse lung diseases.
- TBNA: TBNA may be used to obtain tissue samples from paratracheal, hilar, and peribronchial areas. For visible tumors, the yield of TBNA and forceps biopsy is similar. A protected transbronchial needle is passed through the working channel of the bronchoscope and positioned with the needle perpendicular to the endobronchial wall. The tracheal wall, carina, main stem bronchus, or major spur is pierced with a quick thrust. Suction is then applied to the proximal end of the needle sheath with a 20-mL syringe containing 2 mL

of saline solution. The needle and sheath are removed from the bronchoscope, and the specimen is collected into a container for cytologic analysis. If a dry syringe is used, the specimen is smeared on a glass slide before the examination. At each biopsy site, two or three punctures are commonly made, employing a new needle for each location.

- Recommendations for bronchoscopy during mechanical ventilation through the endotracheal tube. Insert a connection between the endotracheal tube and the ventilator tubing to slide the bronchoscope. Volume-controlled ventilation is usually preferred. Set the fraction of inspired oxygen (FiO_2) at 100%, and remove or reduce positive end-expiratory pressure, except in very severe respiratory failure. Increase respiratory frequency and decrease tidal volume; increase percent inspiratory time. Set the peak pressure alarm to a level to allow adequate ventilation. After the procedure, return all ventilator parameters to their initial values. Over the first 30 minutes after the termination of bronchoscopy, gradually reduce the applied FiO_2 to the prebronchoscopy requirements as long as the patient can maintain an arterial oxygen saturation of hemoglobin measured by a pulse oximeter (SpO_2) at $>92\%$.
- Other procedural considerations. Enteral feeding or oral food intake should be suspended for at least 4 hours before the procedure. Asthmatic subjects should be premedicated with a bronchodilator before the procedure. Platelet count and coagulation times should be checked before performing bronchoscopy in patients in whom a biopsy is anticipated.

AFTERPROCEDURE

Postprocedure Care

- Monitoring
 - Level of consciousness
 - Medications administered
 - Subjective responses (e.g., pain, discomfort, and dyspnea)
 - Blood pressure, heart rate, rhythm, and changes in cardiac status
 - SpO_2 and supplemental oxygen use
- Close surveillance to promptly detect and treat any new findings presenting over the first hours after the end of the procedure (see complications)
- Nothing by mouth for 2 hours

Complications

- Common
 - Hypoxemia; it commonly occurs during bronchoscopy; the insertion of a bronchoscope into the airways reduces the cross-sectional area available for airflow, thus increasing the airway resistance and the work of breathing. Continuous suctioning through the instrument evacuates respiratory gases and

decreases the residual functional capacity, leading to the development of hypoxemia. Hypoxemia may be more severe after BAL, owing to ventilation-perfusion abnormalities induced by the instillation of a saline solution; the decrease in arterial oxygen partial pressure resulting from bronchoscopy may last a few minutes to several hours after the removal of the bronchoscope

- Mild hypercapnia
- Increased airway resistance
- Modest alterations in systolic blood pressure, consisting of either a decrease (generally related to sedation) or an increase from the baseline
- Slight increase in heart rate
- Infrequent
 - Periprocedural adverse drug reactions
 - Bronchospasm or laryngospasm, particularly in patients with preexisting reactive airway disease
 - Major cardiac rhythm abnormalities; the risk of arrhythmias is the greatest during the passage of the bronchoscope through the vocal cords in nonintubated patients, especially if hypoxemia is present.
 - Bradycardia or other vagally mediated phenomena
 - Epistaxis, in transnasal procedures
 - Pneumothorax; it is very uncommon after bronchoscopy but has an increased incidence in patients undergoing TBLB
 - Significant bleeding, defined as more than 50 mL of blood loss; the likelihood of hemorrhage from bronchoscopy increases when biopsy or brushing procedures are performed; patients at a higher risk of bleeding include those with uremia, immunosuppression, pulmonary hypertension, liver disease, coagulation disorders, or thrombocytopenia
 - Fever and chills; fever rarely occurs after bronchoscopy (1.2%) but occurs more commonly (10% to 30% of cases) after BAL; fever is thought to be generally caused by the release of proinflammatory cytokines from alveolar macrophages
 - Nausea, vomiting
 - Cross-contamination of bronchoscopes
- Serious, rare complications
 - Death

OUTCOMES AND EVIDENCE

- Outcome after bronchoscopy depends on the patient's coexisting condition; flexible bronchoscopy is associated with a 0.3% incidence of major complications and a mortality rate of 0.02%; major complications requiring resuscitative measures are significantly more likely with rigid bronchoscopy as compared with flexible bronchoscopy.
- The most frequent life-threatening complications leading to death following bronchoscopy include airway problems, cardiovascular events, and bleeding.

BEFORE PROCEDURE

Indications

- Diagnosis of pneumonia
 - Viral, bacterial, fungal, pneumonias
 - Quantitative cultures for ventilator-associated pneumonias
 - Infiltrates in an immunocompromised host
- Evaluation of diffuse lung infiltrates and evaluation of interstitial lung disease
- Suspected pulmonary hemorrhage
- Suspected malignancies
- Both bronchoalveolar lavage (BAL) and protected specimen bronchial brushing (PSB) use quantitative culture techniques to differentiate between airway colonization and true pulmonary infections.¹⁻⁴

Contraindications

- Acute respiratory distress syndrome with hypoxemia
 - May cause derecruitment in noncompliant severe air space disease
 - Cardiac arrhythmias, hypoxemia, bronchospasm
- Bronchopleural fistula
 - May not be able to return adequate specimen for analysis

Equipment

- Flexible fiberoptic bronchoscope
- Sterile saline
- Vacuum suction source
- Suction tubing
- Syringes: 10 mL, 20 mL, or 60 mL slip-tip
- Sterile collection trap
- Lidocaine, 1% to 2% for topical anesthesia, if needed
- Medications for procedural conscious sedation, if needed
- Burman airway or oral airway
- Supplemental oxygen
- Endotracheal bronchoscope attachment

ANATOMY

- If performed on native airways, the first structures to be identified are the epiglottis and the vocal cords.
 - Topical anesthesia using 1% to 2% lidocaine is administered through a bronchoscope to the vocal cords.
- Next landmark to be located is the trachea and the identification of the carina.
 - Additional administration of 1% to 2% lidocaine to the carina.
- Right and left main bronchi are identified, and location of desired BAL specimen is obtained at the site where purulent material is present or where infiltrate is visible on the chest x-ray.⁵
- If unsure as to which lobe needs to be sampled, the posterior portion of the right lower lobe should be sampled first. Autopsy

studies indicate that pneumonias in intensive care unit (ICU) patients often involve this lobe.⁶⁻⁹

- To obtain the BAL, the bronchoscope is advanced to the farthest segment of the affected bronchus until it cannot be advanced any farther.

PROCEDURE: BRONCHOALVEOLAR LAVAGE

See Video E14-1.

- Obtain informed consent, including for topical anesthesia of airways and/or conscious sedation.
- Prepare for conscious sedation, and use telemetry devices to monitor continuous pulse oximetry, intermittent blood pressure cuff measurement, and supplemental oxygen (via nasal cannula or non-rebreather mask or ventilator).
- For patients at risk of bronchospasm, premedicate with bronchodilators, and treat airways with 2% lidocaine via an atomizer.
- Review chest radiograph to identify ideal location for BAL. Right middle lobe or lingula is preferred in supine patients, with the right lower lobe also serving as a possible direct path for aspiration.
- Prepare the bronchoscope, collection trap, tubing, and sterile saline.
- Anesthetize vocal cords in nonintubated patients and carina in intubated patients with 2% lidocaine (5 mg/kg maximum).
- Avoid suctioning prior to obtaining BAL specimen to avoid specimen contamination.
- Advance the bronchoscope until wedged in the desired subsegmental bronchus.
- Flush 20 mL sterile saline through the wedged bronchoscope, watching for the flow of saline into distal airways and also for the blanching of tissues.
- Obtain sample immediately after the wash, ensuring the return of the lavage specimen into the collection trap.
- Slight repositioning of bronchoscope tip can allow for better fluid return.
- Intermittent pulsing of suctioning can reduce distal airway collapse.
- Repeat 20-mL sterile saline washes as necessary to obtain adequate sample (usually a total of 30-50 mL, which is usually 40%-70% recovery of total instilled volume).
- Larger volume aliquots for lavage can be used (as much as 50 mL per lavage, with total volume of 120 mL in 3 to 6 aliquots).^{5,10}
 - Estimated alveolar surface area distal to the wedged bronchoscope is 100 times greater than the peripheral airway.
- Fluid return of the BAL can affect the validity of results, and small returns may contain only diluted material from the bronchus rather than the alveoli, resulting in false negatives.¹¹
 - In patients with highly collapsible airways, including patients with chronic obstructive pulmonary disease (COPD), the amount of negative pressure applied via the bronchoscope to aspirate sample can limit the amount of sample returned and may give rise to a false negative result.
- Sensitivity of BAL is 73% and specificity is 82% in diagnosis of pneumonia.¹²⁻²³

PROCEDURE: PROTECTED SPECIMEN BRONCHIAL BRUSHING

- Same procedure as bronchoalveolar lavage except for the use of an endobronchial catheter wedged in the tracheobronchial tree.
- The brush is rubbed against areas of suspected infection and then removed from the procedure port of the bronchoscope.
- The brush is then aseptically cut into a measured volume of sterile diluent (usually 1 mL of preservative-free sterile saline).^{10,24}
- Double-lumen catheter brush systems with single-sheathed or telescoping plugged catheter tips with distal occluding plugs are used.²⁴⁻²⁶
- Quantitative cutoff is 10^3 colony-forming units per milliliter (CFU/mL).
- Sensitivity of protected specimen bronchial brushing for pneumonia is 89% (95% confidence interval [CI], 87%-93%) and specificity is 94% (95% CI, 92%-97%).^{13,27-33}

AFTER PROCEDURE

Postprocedure Care

- Patients are continuously monitored until full recovery from conscious sedation.
- Ventilated patients are placed on 100% FiO₂ during the procedure and weaned back to previous FiO₂ levels, as tolerated. Derecruitment is possible and may require recruitment maneuvers.
- Specimen handling
 - For PSB, the brush should be aseptically cut into 1 mL of preservative-free sterile saline.^{10,24}
 - For BAL, the specimen container should be sent for analysis within 30 minutes, although refrigeration can prolong transport and analysis.^{34,35}
- The specimen should be obtained before new antibiotics are administered.
 - Even a few doses of antibiotics can result in negative microbiological cultures.³⁶
 - Quantitative culture techniques of distal pulmonary secretions with minimal or no upper airway contamination.^{1,2}

- BAL and PSB culture sensitivities are lowered if antibiotic therapy has already been initiated.³⁷⁻³⁹
- These techniques do not retrospectively identify resolving pneumonia or assess the adequacy of therapy.^{9,40-43}

Complications

- Common
 - Cough
 - Transient infiltrates that typically resolve in 24 hours
 - Transient decrease in PaO₂
- Infrequent
 - Transient fever, chills, myalgias⁴⁴
- Serious, rare complications
 - Derecruitment and hypoxemia resulting in intubation and positive pressure ventilation or increase in ventilator requirements⁴⁵⁻⁴⁸
 - Pneumothorax

OUTCOMES AND EVIDENCE

- Quantitative culture techniques are necessary to differentiate infecting organisms from pharyngeal contaminants.⁴⁹⁻⁵³
 - Significant BAL culture concentrates are at least 10^5 to 10^6 CFU/mL.^{2,6,54-57}
 - Significant PSB culture concentrates are at least 10^3 bacteria.¹⁰
- A small number of false positive BAL and PSB results can be seen even when using strict criteria to distinguish between airway colonization and deep lung infections of 10^3 to 10^4 CFU/mL.⁵⁸
- False negative BAL and PSB results occur when
 - Bronchoscopy is performed at an early stage of infection, and bacterial load is not high enough to reach diagnostic significance.
 - Specimens are obtained from unaffected segments of lung.
 - Specimen processing errors occur.
 - Specimens are obtained after initiation of a new class of antibiotics.
- Consider repeat sampling for persistently symptomatic patients with initial negative quantitative concentrations.⁵⁹

BEFORE PROCEDURE

Indications

- Requirement of a temporary or long-term artificial airway for prolonged mechanical ventilation
- Management of secretions
- Nonemergency airway obstruction

Contraindications

- Inability to clearly palpate and identify tracheal landmarks
- Enlarged thyroid or other neck mass
- Active infection at the site
- Emergency need for airway
- Positive end-expiratory pressure (PEEP) greater than 20 cm H₂O
- Previous surgical scar
- Bleeding
- Increased intracranial pressure
- Clinically significant coagulopathy
- Documented tracheomalacia
- Cervical irradiation
- Morbid obesity
- Maxillofacial or neck trauma
- Lack of cervical spine clearance
- Inability to extend the neck because of a cervical spine fracture
- In addition, we do not perform the procedure in patients younger than 16 years of age because of the scarcity of experience reported in pediatric patients.

Equipment

- Equipment required at the bedside to perform the percutaneous dilatational tracheostomy (PDT) procedure should include
 - PDT introducer set (Ciaglia Blue Rhino Percutaneous Tracheostomy Introducer Set #C-PTIS-100-HC, Cook Critical Care, Bloomington, Indiana)
 - Bronchoscope with video monitor display and bronchoscopy endotracheal tube adapter
 - Continuous electrocardiographic (ECG) monitor
 - Blood pressure monitoring device
 - Pulse oximeter
 - Free-flowing intravenous catheter
 - Mechanical ventilator
 - Suction
 - Resuscitation ("crash") cart
 - Open tracheostomy instrument tray (unopened)
- Supplies required at the bedside include
 - Chloroprep or other solution for skin preparation
 - 4 × 4-inch bandages
 - Syringes and needles
 - Sterile gowns and gloves
 - Shiley Percutaneous Dual Cannula Cuffed Tracheostomy Tube
 - Kelly clamp
 - Sterile saline solution

- Medications required at the bedside include
 - 1% Xylocaine with epinephrine 1 : 100,000
 - Midazolam, 1 mg/mL injectable or other appropriate sedative
 - Morphine, 10 mg injectable or another appropriate narcotic
 - Vecuronium, injectable, or other appropriate paralyzing agent
 - Sterile normal saline flush solution
 - Other medications at the discretion of the PDT operator
- The choice of a PDT introducer set may vary by institution; ours includes the set listed only because we have significant experience with it. However, it is critical that only one type of PDT introducer set be in use in an institution at any given time. To ensure maximum safety, every aspect of this procedure must be standardized, especially the equipment used.

ANATOMY

The thyroid notch and cartilage are palpated, followed by the cricothyroid membrane and cartilage and the tracheal rings. It is essential that the tracheal puncture be made inferior to the cricoid cartilage landmark. If the second and third tracheal rings cannot be distinctly identified, the procedure is aborted, and an open tracheostomy is performed.

PROCEDURE

See Video E15-1.

- A single tapered PDT dilator and kit with simultaneous intraoperative bronchoscopy is used.
- Two teams are used simultaneously. One team manages the endotracheal tube, and the other manages the placement of the tracheostomy tube.
- The patient's physiologic parameters, including arterial oxygen saturation, are monitored continuously throughout the procedure by the intensive care unit (ICU) nurses and a respiratory therapist.
- Intravenous sedation and paralytic agents are administered as required, and the patient is fully ventilated via an endotracheal tube.
- The patient is positioned with the neck slightly extended and a pillow under the shoulders.
- Under sterile conditions, the PDT dilators and tracheostomy tube must be prepared.
- The Blue Rhino tracheal dilator is water activated, so it is dipped in sterile saline or water to enhance its lubricant coating.
- The Shiley Percutaneous Dual Cannula Cuffed Tracheostomy Tube is designed specifically to be used with the Cook Percutaneous Tracheostomy Introducer Set. Depending on the size of the patient, it is prepared by inflating the balloon to ensure the integrity and then collapsing the balloon by withdrawing all air.
- The tracheostomy tube, with the cuff, completely deflated, is inserted over the introducer dilator as one unit, placed 2 cm from the tip of the dilator, and then lubricated with sterile gel. The Shiley's tapered distal tip and inverted cuff shoulder are specifically designed for easier insertion. It is important that the tracheostomy tube be placed exactly 2 cm from the tip. If it is placed more than 2 cm from the tip, it will likely not enter the trachea. If it is advanced too far and placed less than 2 cm from the tip, the trachea may be damaged upon insertion.

- The neck is prepared with Chloroprep.
- The dermis and subcutaneous tissues are infiltrated with 1% lidocaine with epinephrine.
- The upper airway endoscopist will then introduce the bronchoscope into the endotracheal tube.
- The endotracheal tube is untaped, the cuff deflated, and the tube is then withdrawn until the tip lies just below the vocal cords. The utmost care is taken to avoid withdrawing the endotracheal tube too far, which could result in extubation of the patient. We recommend that the bronchoscope remains near the tip of the endotracheal tube but entirely within it to prevent inadvertent puncture or spearing of the bronchoscope by the puncture needle.
- The PDT operator verifies the patient's neck anatomy, starting with palpation of the thyroid notch and cartilage and then moving down to the cricothyroid membrane and cartilage and the tracheal rings.
- The anatomy is reconfirmed with digital palpation of the cricoid cartilage because it is essential that the tracheal puncture is made inferior to this landmark. If the second and third tracheal rings cannot be distinctly identified, the procedure is aborted, and an open tracheostomy is performed.
- A 2-cm horizontal skin incision centered between the second and third tracheal rings is made, and the midline subcutaneous tissues are dissected bluntly with a hemostat until the pretracheal fascia is exposed.
- The PDT operator reconfirms the tracheal anatomy by direct palpation through the incision. The trachea is then punctured between the second and third tracheal rings with a 14-gauge cannula-over-needle from the PDT kit.
- Tracheal penetration is confirmed by visualization with the bronchoscope, as well as aspiration of air from the needle.
- The needle is removed, and a J-tip guide wire is then introduced into the trachea through the cannula and visualized with the bronchoscope. The puncturing cannula is then withdrawn.
- A small 14F dilator is then introduced over the guide wire to widen the tracheal opening. The dilator is then withdrawn.
- An 8F guiding catheter is introduced over the guide wire to the skin level mark on the guide wire. The guiding catheter and guide wire are introduced as a unit into the trachea until the safety ridge on the guiding catheter is at the level of the skin. The positioning of the guiding catheter is confirmed by aligning the proximal end of the catheter with the proximal gray mark on the guide wire. This positioning is critical to prevent displacement of the J-tip guide wire and possible trauma to the posterior tracheal wall during subsequent dilations.
- The lubricated Blue Rhino tracheal dilator is then passed over the cannula and guide wire and into the trachea to dilate the tract fully. This requires forceful pressure to accomplish smoothly.
- The tracheal dilator is then withdrawn, but the guiding catheter and guide wire remain in place.
- The tracheostomy tube and introducer dilator are threaded over the guide cannula and guide wire as one unit and inserted into the trachea under direct bronchoscopic visualization.
- The introducer dilator, guiding catheter, and guide wire are then withdrawn, leaving the tracheostomy tube in place.
- The inner cannula is then inserted, and the cuff is inflated.
- The PDT operator continues to hold the tracheostomy in place with one hand and never removes it until the tracheostomy tube is sutured in all four corners to ensure the tube is not inadvertently displaced.
- The bronchoscope is then inserted into the tracheostomy tube to confirm placement within the trachea.
- The ventilator tubing is then connected to the tracheostomy. The appropriate tidal volume and oxygen saturation are confirmed.
- The tracheostomy tube is sutured to the neck with 4-0 gauge nylon sutures placed in each corner.
- Once the tracheostomy tube is sutured in all four corners and also secured around the neck with umbilical tape, the endotracheal tube is removed. Make sure that the umbilical tape is not placed too tightly, as a skin breakdown can result. At least one finger should be able to fit between the umbilical tape and the skin.

AFTER PROCEDURE

Postprocedure Care

- A simple 4 × 4-inch gauze dressing is partially slit and placed between the tracheostomy wings and the skin.
- A chest radiograph is not indicated unless the procedure was complicated.
- A close observation by the nursing staff is required to detect bleeding externally at the tracheostomy site or internally into the airway. The bleeding must be immediately reported to the PDT operator and the ICU physician and must be carefully evaluated and controlled.
- Bleeding into the airway can lead to the formation of an obstructing clot at the carina, with fatal consequences.

Complications

- Common
 - Bleeding
 - Subcutaneous emphysema
 - Extratracheal cannulation
 - Brief episodes of hypoxia
 - Stomal infections
- Serious complications
 - Puncture or laceration of the posterior tracheal wall
 - Loss of airway
 - Conversion to open tracheostomy
 - Serious hemorrhage due to a severed blood vessel
 - Death

OUTCOMES AND EVIDENCE

- PDT is a safe procedure, with morbidity and mortality rates equivalent to or lower than those of an open tracheostomy.
- Numerous early studies reported the morbidity of PDT to be between 3% and 19%, compared with a complication rate of 26% to 63% for open tracheostomy.
- Recent studies have found the overall mortality for a tracheostomy to be 37%, with no statistically significant difference in mortality for PDT compared with an open tracheostomy.
- The incidence of wound infection has been reported to be 6.6%.
- One study compared PDT to surgical tracheostomy (ST) and found that PDT was associated with a significantly reduced risk of wound infection (OR, 0.28; 95% CI, 0.16-0.49; $P < 0.0005$).
- One report found the overall incidence of bleeding to be 5.7%, with no significant difference in incidence when comparing PDT to ST.

BEFORE PROCEDURE

Indications

- Short-term hemostasis and stabilization of patients until definitive therapy can be arranged
- Failure to achieve hemostasis after endoscopic treatment of bleeding esophageal varices
- As a temporizing measure when endoscopic treatment is not immediately available or emergency transcatheter intrahepatic portosystemic shunt is being arranged

Contraindications

- Known or suspected esophageal tear
- Recent esophageal surgery
- Known esophageal stricture
- Use with caution in patients with a hiatal hernia

Equipment

- Minnesota tube (a modified Sengstaken-Blakemore tube with esophageal suction port above the esophageal balloon)
- Sengstaken-Blakemore tube (has a 250-cc gastric balloon and esophageal balloon and a single gastric suction port)
- Linton-Nachlas tube (has a single gastric 600-cc balloon)

PROCEDURE

See Video E16-1.

- If not already done, proceed with endotracheal intubation for airway protection.
- Ensure all equipment is available and ready.
 - Tube of choice
 - Large-volume syringe
 - A traction pulley system
 - Adequate suction
- Test the integrity of the gastric and esophageal balloon(s) of the tube by inflating them fully. Deflate the balloon(s), making sure all the air is out.
- Insert the tube transnasally, and advance it into the full length of the esophagus. If the transnasal route cannot be used, transoral insertion is also acceptable. Avoid transnasal placement in coagulopathic patients if possible.
- Put 30 to 50 mL of air through the gastric port, clamp it, and check for the correct placement. The partially inflated gastric balloon must be clearly seen below the diaphragm on a chest x-ray. Do not overinflate the gastric balloon during this step, as accidental full balloon inflation in the esophagus would likely lead to esophageal rupture.
- Once placement is confirmed, inflate the gastric balloon fully (500-700 mL).
- Pull the tube back slowly until meeting with resistance. Traction can then be applied in a number of ways: with an overhead frame pulley system (such as the one used for skeletal traction) or by securely taping the tube to the nose. More creatively, the patient can be fit with a football helmet or a catcher's mask, which are then used to stabilize the tube. The frame pulley system has the

advantage that the degree of traction can be accurately measured. A 1-kg weight is enough (a 1-L bag of a crystalloid solution can be conveniently used).

- Connect the suction ports to suction. If the tube used has a gastric and esophageal suction ports, place them to suction separately, and monitor the output. If the blood continues to come out of the esophageal port, inflate the esophageal balloon to 25 to 35 mm Hg (this is best achieved by attaching a three-way stopcock to the inflation port, with one of the limbs connected to a transducer for continuous pressure monitoring).

AFTER PROCEDURE

Postprocedure Care

- If inflated, monitor the pressure of the esophageal balloon at least once a day but preferably continuously.
- Monitor the angle of the tube with respect to the nose, and adjust accordingly to prevent pressure necrosis.
- The tube should be removed as early as possible. However, it is unknown how long a tube can safely remain in place, but it can be left in place 24-48 hours, and the gastric balloon should be deflated every 12 hours to check for rebleeding.
- To remove the tube, the steps are reversed. First, deflate the esophageal balloon (if using a tube that has one), keeping the gastric balloon on traction. If bleeding does not resume, one can proceed to discontinue the traction while keeping the gastric balloon fully inflated for an additional 24-48 hours. If there is no rebleeding, then the gastric balloon is deflated, and the tube is removed.
- If bleeding continues, then reinflate the appropriate balloon.

Complications

- The incidence of tube-related complications being the direct cause of death is 0%-20%.
- Common
 - Esophageal and fundal mucosal ulcerations
 - Pressure necrosis of the alae nasae
 - Nasopharyngeal bleeding
- Infrequent
 - Aspiration pneumonia
- Serious, rare complications
 - Esophageal perforation
 - Airway obstruction
 - Tube migration with laryngeal obstruction or tracheal rupture
 - Impaction of the balloon requiring surgery for removal

OUTCOMES AND EVIDENCE

- Primary hemostasis can probably be achieved in about 30%-90% of cases.
- The variability in success rates are due to patient selection, concomitant use of other therapies, and experience of staff using the tubes.
- The evidence is weak because most studies are at least two decades old, employed different types of tubes (e.g., Sengstaken-Blakemore, Linton, or Minnesota), and weren't likely randomized. This situation is unlikely to change, as balloon tamponade is seldom needed today.

■ BEFORE THE PROCEDURE

Indications

- Inability to maintain adequate volitional intake in the setting of a functional gastrointestinal tract and/or
 - Acute critical illness expected to require more than 2-day intensive care unit (ICU) stay
 - Daily nutritional requirements are not met for more than 7 days in adults
 - Poor nutritional status and nutrient depletion
 - Unintentional weight loss of more than 5 lb or 5% of body weight over 1 month or body mass index (BMI) less than 18.5 kg/m²

Contraindications

- Inability to tolerate enteral nutrition
 - Mechanical bowel obstruction
 - Severe ileus
 - Short gut
 - High-output fistula
 - Peritonitis
 - Major gastrointestinal bleeding
- Hemodynamic compromise (e.g., starting or escalating dose of vasopressors in previously stable patient, large volume fluid or blood product resuscitation)
- Severe cranial or facial fractures
- Esophageal obstruction or recent surgery
- Esophageal or gastric varices
- Coagulopathy
- Patient not cooperative with nasoenteric feeding tube placement

Equipment

- Tube
 - Nasogastric sump tube (14F-18F)
 - Nasoenteric feeding tube with stylet and/or metal weighted tip
- Lubricant
- Gloves
- Gown with long sleeves
- Eye protection
- Emesis basin
- Syringe
 - 60-mL Toomey syringe if inserting a sump tube
 - 10-mL Luer-Lok syringe if inserting a nasoenteric feeding tube
- Stethoscope
- Adhesive device
 - Tape
 - Bridle
- Optional
 - Lidocaine jelly
 - Proton pump inhibitor (e.g., metoclopramide or erythromycin)
 - End-tidal CO₂ detector
 - pH testing strip

■ ANATOMY

The successful placement of the feeding tube requires that it pass through the nasal cavity, pharynx, esophagus, and into the stomach. The nasal cavity is the continuation of each nostril and is separated into halves by the nasal septum. The pharynx consists of a space that extends from the internal nares down to the inferior border of the cricoid cartilage. At this level, it divides into the esophagus and larynx. The esophagus continues until it terminates in a smooth muscle sphincter that separates the lower esophagus from the stomach. Typically, the lower esophageal sphincter lies 40 cm from the incisors. The pylorus lies approximately 60 to 65 cm from the incisors. Markers are inscribed on the feeding tube to facilitate tube advancement to the appropriate depth.

■ PROCEDURE

See Video E17-1.

- Position patient
 - If awake, place in a seated position.
 - If intubated or unable to comply with instructions, place supine, and elevate the head of the bed to 45 degrees.
- Coat tube with lubricant.
- Consider applying lidocaine jelly to the back of the nares.
- Insert tube into the nares.
- As the tube enters the hypopharynx, ask the patient to tilt head forward and swallow.
- Once inserted to 35 cm, tape the tube in place and confirm the intrasophageal position
 - Obtain a chest x-ray (CXR) or
 - Attach an end-tidal CO₂ detector to the end of the tube. If the indicator turns yellow (positive for CO₂), remove the tube and reposition. If the indicator remains purple (negative for CO₂), proceed.
- Advance the feeding tube to 55 cm, and tape in place if intending to initiate gastric feeding.
- If intending to initiate gastric feeding
 - Check the position of the tube.
 - Use a stethoscope to auscultate the left upper quadrant.
 - Insufflate air into the tube using a syringe.
 - If the passage of air into the stomach is heard, tape the tube in place. If unable to hear the passage of air, reposition the tube.
- If intending to initiate postpyloric feeding
 - Place the patient in the right lateral decubitus position.
 - Consider administering a prokinetic agent.
 - Advance the tube to 80 to 100 cm.
- Other adjuncts for assistance with the positioning of the tube
 - Magnets
 - Endoscopy
 - Bedside fluoroscopy

■ AFTER PROCEDURE

Postprocedure Care

- Obtain CXR to confirm the position of the tube.
- Remove the stylet.

- Attach the tube securely to the nose using tape.
- Consider placing a bridle.

Complications

- Common
 - Unplanned removal of the feeding tube
 - Tube obstruction
- Infrequent
 - Trauma from insertion of the tube
 - Bleeding from the nasal turbinates
 - Retropharyngeal hematoma
 - Gastrointestinal bleeding
 - Otitis media
 - Sinusitis
 - Arrhythmia
- Serious and/or rare
 - Placement into the cranium, trachea, and bronchus

- Perforation of the bronchus (pneumothorax), esophagus, stomach, and duodenum

OUTCOMES AND EVIDENCE

- Early nutrition support therapy, especially using the enteral route, may improve patient outcomes in the major elective gastrointestinal surgery and surgical critical care population by reducing infectious complications, length of stay in the ICU, and disease severity.
- Placement of the nasoenteric feeding tube results in complications in approximately 2% to 5% of cases. Experienced practitioners who verify the placement of the tube before initiating feeding can reduce the incidence of adverse sequelae resulting from the inadvertent insertion of tubes into unintended locations.
- The decision to initiate gastric versus postpyloric feeding remains controversial. Evidence of aspiration, history of gastric atony, or intolerance of gastric feeding should prompt physicians to consider placing a postpyloric feeding tube.

BEFORE PROCEDURE

Indications

- Suspicion of a central nervous system (CNS) infection
- Suspicion of a subarachnoid hemorrhage
- The need to obtain cerebrospinal fluid to diagnose other inflammatory or degenerative CNS diseases
- Reduction of cerebrospinal fluid (CSF) pressure in pseudotumor cerebri

Contraindications

- Absolute
 - Intracranial or spinous (especially intramedullary) mass (e.g., tumor, abscess). If there is a concern, an imaging study should be performed before the procedure. A rapid decrease in intracranial pressure from the withdrawal of CSF could precipitate herniation or worsening of spinal cord function if a mass lesion is present.
 - Overlying skin infection
 - Lumbar spine disease
- Relative
 - Coagulopathy and/or thrombocytopenia, because an epidural hematoma can develop at the puncture site. Fresh frozen plasma and platelets should be infused to correct hematologic abnormalities before the procedure. If a coagulopathy is discovered after the procedure, therapy should still be administered, because bleeding can occur for many hours.
 - If a lumbar puncture is being performed to evaluate a patient with an aneurysmal subarachnoid hemorrhage, withdraw the smallest possible amount of CSF to obtain the necessary laboratory tests. Reducing the CSF pressure could precipitate rebleeding.
 - Uncooperative patient

Equipment

- Lumbar puncture tray or individual components (see later)
- Chlorhexidine or povidone-iodine prepping solution
- Sterile drape with a central opening
- 1% Lidocaine and a syringe with 25- and 22-gauge needles for local anesthesia
- 20- or 22-gauge spinal needle
- Manometer
- Tubes for CSF collection

ANATOMY

The site of the intended puncture is either the L4-5 or L5-S1 interspace. These can be determined as follows. The L3-4 interspace can be located by drawing an imaginary line between the posterior iliac crests. This is usually the most rostral space employed because the adult spinal cord ends at L2. Walk the fingers down the spinous processes to identify the L4-5 and L5-S1 interspaces, and mark them on the skin. Note that during lumbar spine disease, the question of a spinal mass or an overlying skin infection prevents the lumbar approach; a lateral

cervical approach can be performed by a physician trained in this technique. In cases of a difficult lumbar puncture in obese patients, a bedside ultrasound can be helpful.

PROCEDURE

See Video E18-1.

- Place the patient in the lateral decubitus position with knees flexed to the abdomen and head flexed with the chin toward the chest.
- Position the patient's back as close as possible to the edge of the bed nearest the examiner.
- Before preparing the skin, locate the L4-5 and L5-S1 interspaces and mark them.
- The skin should then be prepared with chlorhexidine or povidone-iodine. The preparation should proceed outward in a spiral and cover several interspaces in case multiple attempts are necessary.
- Drape the patient's back with a sterile sheet with an opening to the prepared area so that it covers the posterior iliac crest.
- Anesthetize the skin with 1% lidocaine using a 25-gauge needle, which may be exchanged for a longer 22-gauge needle to reach deeper tissues.
- Using a 20- or 22-gauge spinal needle, advance it with the stylet in place to avoid the introduction of epidermal cells into the subarachnoid space.
- Direct the bevel of the needle upward to separate the fibers of the ligamentum flavum. The angle of the needle 15 degrees cephalad and slightly downward toward the bed.
- When the dura is punctured, and a slight "pop" is felt, the stylet should be withdrawn.
- If a free flow of CSF does not occur, the needle can be rotated or may have to be advanced (after replacing the stylet).
- Once the free flow of CSF is obtained, attach a manometer to the spinal needle, usually by way of a stopcock. CSF should rise steadily in the manometer until the opening pressure is reached and respiratory fluctuation can be visualized in the fluid column.
- The patient's legs should be carefully extended and relaxed for an accurate pressure reading.
- Collect four tubes of CSF (3 mL of fluid in each) and send them for appropriate studies.
- In cases of pseudotumor cerebri in which a lumbar puncture has been chosen as a therapeutic modality to reduce the raised intracranial pressure, after quantifying the opening pressure, the removal of 20 mL of CSF is generally recommended and the closing pressure documented.
- Replace the stylet to minimize the possibility of pulling a nerve root through the dura as the needle is removed.
- Withdraw the needle and apply pressure to the puncture site.
- If the subarachnoid space cannot be entered with this technique or the patient cannot lie in the lateral decubitus position, a lumbar puncture can be performed with the patient sitting on the side of the bed leaning forward over a bedside table. However, once free CSF flow occurs, the patient should be returned to the recumbent position for accurate pressure measurements.
- If a patient is unable to bend one leg (e.g., after an angiographic procedure), a lumbar puncture can be attempted in the lateral position with the bottom leg held straight, and the top leg bent into the abdomen and supported with a pillow.

AFTER PROCEDURE

Postprocedure Care

- Allow the patient to lie flat for 1 to 3 hours after the procedure to minimize the risk of post–lumbar puncture headache. Argument persists regarding the value of prone versus supine positioning on the incidence of a headache and about the use of varying sizes and types of needles.

Complications

- Common
 - Headache
 - Bleeding from the puncture site
- Infrequent
 - CSF leak
 - Infection
 - Subarachnoid cyst

- Serious, rare complications
 - Epidural hematoma formation
 - Cerebral herniation
 - Aneurysmal rebleeding
 - Nerve root injury

OUTCOMES AND EVIDENCE

- To ensure an optimal diagnostic outcome when performing a lumbar puncture, it is wise to check with the laboratory before the procedure if any unusual tests are being performed, because an additional tube or larger volumes or special handling of CSF may be required. Regarding optimal patient outcomes, if a diagnostic lumbar puncture is delayed for imaging in a suspected case of bacterial meningitis, blood cultures should be obtained, and empiric antibiotics should be administered, as CSF cultures can be obtained up to 4 hours after starting treatment.

Jugular Venous and Brain Tissue Oxygen Tension Monitoring

Lucido L. Ponce Mejia, Jovany Cruz Navarro, Santhosh Sadasivan, Shankar Gopinath, Bartley Mitchell, and Claudia S. Robertson

ULTRASOUND-GUIDED INTERNAL JUGULAR VEIN OXYGEN SATURATION (Sjvo₂) CATHETER PLACEMENT: BEFORE PROCEDURE

Indications

- Severe traumatic brain injury
- Subarachnoid hemorrhage
- During neurosurgical and cardiovascular procedures in which, cerebral blood flow may be reduced
- Detection of arteriovenous fistulas
- To titrate hyperventilation in patients with increased intracranial pressure

Contraindications

- Absolute
 - Infection of the placement site
 - Suspected pathologic conditions affecting the internal jugular vein or superior vena cava
 - Severe coagulopathy
- Relative
 - Cervical spine injury
 - Tracheostomy
 - Recurrent sepsis
 - Hypercoagulable state
 - Sensitivity to heparin if a heparin-coated catheter is used
 - Distorted anatomic landmarks

Equipment

- Sterile gowns
- Sterile gloves
- Mask
- Betadine or chlorhexidine solution
- Commercially packaged catheterization kits are available; kits may include
 - Drapes
 - Disinfectant sponges
 - Gauze pads
 - Sutures with needles
 - Guide wire
 - Scalpel
 - Vein dilator
 - Penetration, guide, and anesthetic syringe, as well as a 1% or 2% lidocaine anesthetic solution
- Ultrasound machines with high-resolution vascular transducers are preferred for this procedure.
- Sterile transduction gel, acoustically transparent sterile transducer sheath, and sterile rubber bands or clips to secure sheath around transducer
- 5.5F fiberoptic intravascular catheter (Opticath catheter)

- The catheter contains the fiberoptics for light transmission, a distal lumen for pressure reading, sampling, or infusion, and a thermistor for temperature measurement.
- Optical module (to connect to bedside monitor)
- Introducer kit

ANATOMY

The venous sinuses of the brain drain out of the skull through the jugular foramina and into the internal jugular veins. Immediately distal to the jugular foramen, the vein dilates, forming the jugular venous bulb. The cerebral and cerebellar veins and the veins of the brainstem all open into major sinuses (e.g., superior sagittal, inferior sagittal, straight, right, and left transverse, and occipital sinuses); these terminate in the right and left sigmoid sinuses, which curve downward into a deep groove on the mastoid part of the temporal bone. Finally, they turn forward in the posterior aspect of the jugular foramen to become the jugular bulb of the internal jugular vein.

The trachea is in the midline descending to the sternal notch. The two heads of the sternocleidomastoid muscle and the clavicle form a triangle at the anterior neck. The internal jugular vein may be accessed through this triangle, approximately 2 to 3 cm above the clavicle. Performing a venous puncture higher in the triangle reduces the risk of pneumothorax and allows for better compression of the carotid artery in the case of an inadvertent carotid puncture.

PROCEDURE

See Video E19-1.

- Continuous electrocardiography (ECG) and pulse oximetry
- Place the patient in Trendelenburg position to increase jugular filling and reduce the possibility of an air embolism.
- Avoid this position in patients with increased intracranial pressure (ICP) or congestive heart failure.
- Rotate the patient's head slightly to the contralateral side of the chosen site.
- Perform an ultrasound survey to assess the location and patency of the jugular vein and to determine whether one side has dominant flow. Catheter placement is easier, and continuous oxygen saturation measurements will usually be better on the side with the greatest blood flow.
- The common carotid artery and the internal jugular vein should be easy to identify. You will see the common carotid artery as a pulsating image, and it will be difficult to compress. The internal jugular vein is larger, easily compressible, and nonpulsating. Ensure that the internal jugular vein is patent by gently compressing the vein with the transducer; slight pressure is sufficient to collapse the lumen of the internal jugular vein. Placing the transducer in a cross-sectional position during the ultrasound examination facilitates the interpretation of the resulting images. Many probes have a marker on one side that corresponds to the same side of the image on the screen. This helps the operator identify the correct orientation of the image.
- After you have identified an acceptable site for cannulation, you will need an assistant.

- Follow the Universal Precautions when placing a jugular venous line.
- Prepare the skin using a chlorhexidine-based antiseptic, and cover the area with a sterile fenestrated drape.
- To prepare the ultrasound probe, have the assistant dispense enough acoustic nonsterile gel into a sterile transducer sheath to cover the transducer surface inside the sheath.
- Have the assistant carefully feed the probe into the sheath and through the gel while extending the sterile sheath away from you over the length of the probe wire. Eliminate any wrinkles in the sheath and any air bubbles between the transducer and the sheath. Place the rubber bands to secure the cover sheath in place. To complete the acoustic coupling, apply a small amount of sterile ultrasound gel to the covered ultrasound probe or the patient's skin.
- Identify a convenient sterile area on which the probe can be placed when not in use.
- Position the transducer perpendicular to the skin so that the internal jugular vein is centered in the resulting ultrasound image and between the two heads of the sternocleidomastoid muscle. The ultrasound probe should be held in your nondominant hand.
- Gently palpate the skin to confirm that the puncture will be between the muscle heads and not through one of the heads.
- Using an 18-gauge needle, puncture the skin just below the transducer, being careful not to damage the sterile sheath.
- Slowly advance the needle at a 45-degree angle in an upward direction while watching the ultrasound screen. As you advance the needle, maintain negative pressure in the syringe until the vein is punctured. The needle will appear as a hyperechogenic shadow.
- If you do not aspirate blood as the needle is advanced, slowly withdraw the needle while maintaining negative pressure. The venous puncture may become evident as you withdraw the needle. Occasionally, pressure from the ultrasound probe may compress the vein, making it difficult to enter the vessel.
- As soon as the blood is freely aspirated, place the probe in the predetermined sterile area, stabilize the needle, and disconnect the syringe.
- Confirm that the blood flow is nonpulsatile.

Introducer Insertion

- Using the Seldinger technique, introduce a flexible guide wire through the needle and into the internal jugular vein. Direct the guide wire in an upward direction toward the jugular bulb.
- While holding the guide wire in place, remove the needle. The guide wire can be visualized in both cross-sectional and longitudinal views within the lumen of the internal jugular vein in the ultrasound screen.
- Use the scalpel to make a small incision in the skin to widen the opening.
- Thread the guide wire through the distal opening of the dilator until it exits through the proximal end of the dilator.
- Confirm that it has reached the proximal end of the dilator, hold the wire in place, and advance the dilator through the skin and into the vessel.
- Once the proper placement is achieved, remove the guide wire and the green dilator.
- Hold the proximal end of the guide wire at all times when advancing the dilator or catheter. This avoids complications from the unintended advancement of the guide wire.
- Bleeding frequently occurs after the dilator is withdrawn; minimize it by applying pressure until the bleeding subsides.

Opticath Intravascular Catheter Insertion

- Inspect the sterile package first; if damaged, DO NOT USE.
- Have an assistant remove the outer wrapping, and leave the catheter covered by the inner covering.

- Pass the optical connector to the assistant, who will connect it to the optical module and proceed with the preinsertion calibration. PLEASE NOTE that only *after* verifying with your assistant that the preinsertion calibration was successful should you proceed to the next step. Failure to do so will result in inaccurate readings.
- After a successful preinsertion calibration, the oximetry system is now ready for use. Prepare for the catheter insertion.
- Pull off the remaining inner catheter covering, and pull the red retainer tab to release the catheter.
- Grasp the catheter near the entrance of the black reference assembly, and gently pull it straight out. Care should be taken in removing the catheter, as the fiberoptics may be damaged if the catheter is withdrawn improperly.
- Flush the catheter with sterile solution, using the distal lumen to remove the remaining air.
- The catheter tip should be illuminated with a red light emission before insertion.
- The catheter should then be advanced until resistance is felt; this distance is usually about 13 to 15 cm and indicates the positioning in the jugular bulb.
- The catheter is then pulled back 0.5 to 1 cm to minimize cephalic vascular impact with head movement.
- Connect the distal lumen to a pressure monitoring line.
- When the catheter is in position and blood is flowing, the system will immediately provide SO₂ readings.
- At this time, ask the assistant to perform a light intensity calibration.
- Verify the position of the catheter tip, and secure the catheter to the patient. The optical module should be secured to or near the patient to avoid strain or tension on the catheter.
- Apply the dressing as per hospital protocol.

AFTER PROCEDURE

Postprocedure Care

- Lateral cervical spine x-ray should be used to confirm adequate catheter tip placement, which should be above the C1-C2 level to minimize contamination with blood coming from the facial vein.
- The Opticath intravascular catheter is removed by a physician. It is removed when ICP has been normal for 24 hours without specific treatment.
- The patient must be in the Trendelenburg position.
- Remove the sutures securing the catheter to the skin.
- Carefully pull out the Opticath intravascular catheter.
- Apply pressure to the site for a few minutes to prevent bleeding.
- Apply a sterile dressing.
- Assess for bleeding or signs of infection.
- Dispose of the Opticath intravascular catheter per hospital protocol.
- Clean the optical module and cable for storage.

Complications

- Carotid artery puncture
- Skin hematoma
- Pneumothorax
- Hemothorax
- Jugular vein thrombosis
- Nerve injury
- Catheter misplacement
- Infection

OUTCOMES AND EVIDENCE

- Normal jugular bulb oxygen saturation values are between 55% and 75%.
- <55% indicates relative cerebral hypoperfusion.

- >75% suggests luxury perfusion.
- Please refer to the standard critical care guidelines for management.

BRAIN TISSUE OXYGEN PROBE AND MICRODIALYSIS CATHETER PLACEMENT: BEFORE PROCEDURE

Indications

- Severe traumatic brain injury
- Aneurysmal subarachnoid hemorrhage
- Malignant stroke
- Vasogenic edema
- To assess brain tissue oxygenation, detect brain hypoxia, and for continuous monitoring of brain tissue chemistry (e.g., metabolites and drugs)

Contraindications

- Absolute
 - Infection and/or lack of skin at the site of planned insertion
 - Coagulopathy
- Relative
 - Incompatibility with available magnetic resonance imaging (MRI) system if an MRI of the brain is needed

Equipment

- Sterile gown pack
- Sterile gloves
- Sterile linen pack
- Sterile 4 × 4 gauze bandages
- Mask
- Shave prep kit
- Betadine bottle
- 16-gauge (orange) angiocatheter to tunnel the probe
- Cranial access tray
- One refrigerated combined LICOX probe box
- “Smart card” (enclosed in the sterile LICOX probe container)
- Note: Do not discard the probe packaging before the probe smart card has been removed from the packaging. Use only the smart card supplied with the probe (the serial number on probe should match the number on the smart card). Use of the wrong smart card can cause measurement errors. If the serial numbers do not match, use another LICOX probe box, and return the first one to the vendor.
- #11 blade
- Nylon 3-0 suture
- CMA 70 Brain Microdialysis catheter
- Central nervous system (CNS) perfusion fluid
- CMA 106 syringe
- Surgeon's head light
- Standard surgical suction
- LICOX monitor with a complete set of cables
- Module box and link box and cable (to attach LICOX monitor to bedside monitor)
- Power cord to red AC wall outlet
- CMA 106 Microdialysis Pump with battery

ANATOMY

Ideally, the probe should be placed in the area at risk for brain hypoxia. However, if a computed tomography (CT) scan reveals no areas at risk for hypoxia, the probe may be placed 2 to 4 cm off the midline just anterior to the coronal suture and at least 1 cm from the other probe when possible. Preparation must include shaving the patient's head to a diameter of approximately 2 to 4 cm off the midline just anterior to the coronal suture.

PROCEDURE

- Since these patients are critically ill, vital signs (e.g., invasive blood pressure, central venous pressure, ECG, pulse oximetry, and core temperature) must be continuously monitored.
- The patient must be under sedation throughout the procedure and have intravenous access and mechanical ventilatory support.
- Wash hands. All staff involved in the procedure should wear a surgical mask and gloves throughout the entire procedure.
- After reviewing the patient's CT head scan, the physician will determine the anatomic area for catheter placement.
- As noted earlier, the probe is placed in the area at risk for brain hypoxia, but if the CT scan does not show areas at risk for hypoxia (i.e., diffuse axonal injury), place the probe at least 1 cm from the intracranial pressure probe.
- This area will be prepped with Betadine. Strict sterile field and technique must be maintained throughout the procedure.
- Drape the patient with the sterile blanket.
- Place the patient in a semi-Fowler position, raising the head of the bed to the level of the physician's preference.
- If a ventriculostomy was previously placed, the same incision may be used for probe placement. If no incision exists, make a 3-cm linear incision, carrying it down to the bone.
- Infiltrate the incision with local anesthetic and epinephrine to help control the bleeding from the scalp incision.
- A self-retaining retractor is then inserted to provide good bone exposure.
- The blunt end of the forceps can be used to remove the periosteum.
- Drill the hole in the skull at the desired catheter insertion site, using a hand drill.
- Remove the drill, and rinse the hole with a sterile isotonic solution.
- Incise the dura carefully with a style or a #11 blade, securing hemostasis as necessary.
- Insert the sharp end of the 16-gauge angiocatheter needle from the inside out through the scalp, 5 cm distant from the burr hole.
- Remove only the needle, leaving the angiocatheter.
- Remove the LICOX catheter from its sterile package.
- Remove the probe from the humidity protection chamber.
- Insert the LICOX probe distal tip into the angiocatheter, and tunnel it below the scalp toward the burr hole.
- Pull the angiocatheter completely out of the scalp.
- Using forceps, insert the distal end of the probe into the brain parenchyma. Ensure that the catheter body is not damaged during insertion.
- If necessary, adjust the position of the probe to allow the distal tip of the catheter to be positioned correctly with respect to the insertion site.
- Use a single suture to secure the probe to the scalp near the insertion; this must be done carefully to avoid damaging or dislodging the catheter.
- To place the microdialysis catheter, insert the sharp end of the 16-gauge angiocatheter needle from the inside out through the scalp 5 cm distant from the burr hole and approximately 1 cm from the brain tissue PO₂ probe insertion site in the scalp.
- After removing the protection tube from the shaft, gently flush with the CNS perfusion fluid, both inlet and outlet tubes, and insert a sterile microvial into the microvial holder.
- Tunnel the microdialysis catheter as previously described for the brain tissue PO₂ probe.
- Grip the catheter shaft with the forceps, proximal to the distal end where the delicate membrane is located. An intact membrane is vital for microdialysate return.
- Insert the membrane into the brain tissue through the burr hole used to insert the brain tissue PO₂ probe.
- Fix the tubing to the scalp, using one suture around the catheter.
- Carefully remove the retractor.

- Make sure both probes remain in place.
- At the burr hole site, close the scalp incision using standard closure techniques; this must be done with extreme caution to avoid damaging any of the probes.
- Apply an extra transparent and soft-cloth adhesive dressing or any appropriate dry sterile occlusive dressing.
- Date and initial the dressing.
- Change the LICOX dressing every 48 hours or whenever saturated, using sterile technique including a mask and sterile gloves, and cleanse the insertion site with Betadine swabs from the central line dressing kit.

AFTER PROCEDURE

Postprocedure Care

- Securing of the LICOX cables
 - The cables should be taped to an arm board and then pinned to the patient's gown, allowing enough slack to accommodate movement of the patient for turning and transferring.
 - Plug in the connecting cable to the proximal end of the probe.
 - Connect both ends of the Y cable to the LICOX monitor. Insert the smart card in the card slot.
 - Power on the LICOX monitor.
 - Wait a few seconds for a stable reading; it may take up to 2 hours for reliable readings.
 - Connect the LICOX monitor to the bedside monitor, using the link box and cable.
 - Attach the Luer-Lok connector to the CMA 106 syringe filled with CNS perfusion fluid.
 - Place the CMA syringe in the CMA 106 pump, and close the lid.
 - Inspect the microvial after 6 minutes to see that the microdialysate flows through the catheter.
 - Replace the microvial every hour or as needed.
 - Discard the first two microvials, since this microdialysate is purely CNS perfusion fluid.
 - If the microdialysate contains blood, it may harm the CMA 600 microdialysis analyzer; if this occurs, the catheter must not be used.

- A CT scan of the head should be obtained after the procedure is complete to confirm the location of the probes.
- Discontinuation of the LICOX CMP system
 - It is recommended that LICOX probes not be left in tissue for more than 5 days.
 - The probes should be removed by a physician. Probes are removed after ICP has been normal for 24 hours without intervention.
 - Remove the sutures securing the probe to the scalp.
 - Carefully pull out the probes.
 - Suture the insertion site in the scalp with a single stitch.
 - Assess for bleeding, cerebrospinal fluid (CSF leak), and signs of infection.
 - Clean the skin and apply a sterile dressing.
 - Dispose of the probes per hospital protocol.
 - Clean the cables and attach to the monitor for storage. Blood and debris may be removed from the cables with a towel and aqueous soap solution that also may contain formaldehyde. Disinfectants containing a high percentage of alcohol or phenol will damage the cables.

Complications

- Common
 - Generally, there are no common complications.
- Infrequent
 - Infection and contusion in <2%
- Serious, rare complications
 - Thrombosis and hemorrhage

OUTCOMES AND EVIDENCE

- Normal brain tissue PO₂ values are between 25 and 50 mm Hg.
- <20 mm Hg indicates impending cerebral hypoxia.
- <10 mm Hg indicates critical hypoxia.
- Please refer to the standard critical care guidelines for the management of cerebral hypoxia.
- Normal values for microdialysate are less well defined; please refer to the textbook for further review.

BEFORE PROCEDURE

Indications

- Common
 - Traumatic brain injury (TBI)
 - Subarachnoid hemorrhage
 - Intracranial hemorrhage (ICH)
 - Acute liver failure
 - Hydrocephalus
- Uncommon
 - Meningitis/encephalitis/brain abscess
 - Pseudotumor cerebri
 - Postoperative

Contraindications

- Absolute
 - Anticoagulation
 - Bleeding diathesis
- Relative
 - Scalp infection
 - Lack of specialized healthcare personnel

Equipment

- Flexible catheter or fiberoptic transducer
- Surgical scalpel
- Spinal needle
- Neurosurgical drill/saw
- Surgical scissors
- Retractors
- 14-gauge catheter

ANATOMY

- For brain monitoring, the entry point is located in the superiorly directed midpupillary line, 3 cm lateral to the sagittal suture and 2 cm anterior to the coronal suture on the right (frontal approach). This is the most commonly chosen site because it sits anterior to the motor strip, is lateral to both the superior sagittal sinus and the large bridging veins, and is on the nondominant hemisphere in most patients. If using a posterior approach, the entry point is 6 cm from theinion and 3 cm lateral to the midline. For lumbar monitoring, the L3-4 space is preferred.
- There are four main ways to monitor ICP
 1. Using an external flexible catheter inserted into the lateral cerebral ventricles (i.e., ventriculostomy) as the gold standard method.
 2. Using a catheter (fluid-coupled) or fiberoptic transducer (fluid-uncoupled) placed into the brain parenchyma (i.e., intraparenchymal catheter).
 3. Using a screw or bolt placed through the skull into the subarachnoid space.
 4. Using a sensor positioned in the epidural/subdural space beneath the skull.
- A lumbar drain can also be used to measure ICP and control the CSF outflow if zeroed at the level of the third ventricle.

PROCEDURE

- Ventriculostomy
 - Place the patient in a supine position with the head of the bed elevated to approximately 20 degrees.
 - Shave areas (frontal or posterior) bilaterally.
 - Prepare with a chlorhexidine-alcohol solution, and cover with a sterile drape.
 - Inject lidocaine solution (1%) into the skin and subcutaneous tissue.
 - Make a 1-cm incision with the scalpel and extend down to the bone. Hold the twist drill perpendicular to the skull to make a burr hole, avoiding the brain parenchyma.
 - Once the burr hole is irrigated, insert a spinal needle through the dura to verify that the incision is large enough to accommodate the catheter.
 - Advance the ventricular catheter through the burr hole perpendicular to the brain parenchyma, toward the inner canthus of the ipsilateral eye. Insert the catheter to a depth of approximately 6 cm to enter the frontal horn of the lateral ventricle. If the cerebrospinal fluid (CSF) is encountered before a depth of 6 cm, withdraw the stylet and advance the catheter the remaining distance. If CSF flow is not obtained at 6 cm, additional attempts should be made with the catheter tip directed more medially (i.e., toward the bridge of the nose or the inner canthus of the contralateral eye).
 - Tunnel the external end of the catheter under the scalp to exit through a separate incision approximately 5 to 6 cm from the entry point. Connect the distal end of the catheter to a pressure transducer and/or drainage system. Close the incision wound with sutures, and secure the catheter to the scalp with nylon suture. Apply a sterile nonocclusive dressing to minimize the risk of infection.
 - Zero the pressure transducer (fluid-coupled) at the level of the external auditory meatus.
- Intraparenchymal
 - The placement and tunneling of the device are similar to that of a ventriculostomy, but the depth of insertion depends on the compartment being monitored (e.g., subdural space, parenchyma, or ventricular system).
- Subarachnoid screw or bolt
 - The device is inserted using the same location and technique described earlier for burr hole placement. Once the burr hole is drilled, the dura and arachnoid are opened, and the threaded bolt is placed into the skull abutting the dura. Continuous fluid coupling between the subarachnoid space and an external pressure transducer are recorded through rigid tubing attached to the top of the bolt.
- Epidural/subdural sensor
 - This is inserted via the burr hole into the space between the skull and the epidural lining.
- Lumbar drain
 - Ensure that the patient has a functioning ventriculostomy in place and open cisterns on head CT scan
 - Place the patient in lateral decubitus.
 - Use the same preparation as for brain monitoring.
 - Insert a 14-gauge needle with 10 to 15 degrees of angulation in the cephalic direction, and once the lumbar cistern is entered,

rotate the needle 90 degrees, remove the obturator from the needle, and measure an opening pressure.

- Insert the catheter with a guide wire until the 15-cm mark on the catheter is reached. Remove the needle while maintaining the catheter in the same position. Remove the guide wire from the lumbar drain catheter, and connect the drain to the CSF collecting system.

AFTER PROCEDURE

Postprocedure Care

- If fluid-coupled systems are used, the pressure transducer must be adjusted to the head position to avoid errors in measurement.
- Check for air bubbles, blood clots, or other material occluding the tubing.
- Inspect the drain insertion site to ensure no leakage of CSF around the exit site.
- Sample the CSF daily to detect infection early.
- Normal ICP values are between 0 to 10 mm Hg (under resting conditions).
- *Intracranial hypertension* is defined as a sustained elevation of ICP above 20 to 25 mm Hg for more than 5 minutes.

Complications

- Common
 - Malpositioning
 - Erroneous values (subarachnoid catheters in case of swollen parenchyma and dural flap; epidural catheters when ICP exceeds 30 mm Hg)
 - Erroneous zeroing (intraparenchymal if monitoring more than 5 to 7 days)
- Infrequent
 - Overdrainage (lumbar drain)
 - Radiculopathy (lumbar drain)
- Serious rare complications
 - Infections (e.g., ventriculostomy)
 - Hemorrhage: 0.5% to 10%
 - Brain herniation (lumbar drain)

OUTCOMES AND EVIDENCE

- Monitoring ICP is recommended in critically ill patients with coma (defined by a GCS < 9) after acute brain injury (e.g., trauma, intracranial hemorrhage, encephalitis) with abnormal noncontrast head CT scan (defined by the presence of intracerebral lesions and/or signs of brain edema, such as sulci or cisternal effacement) who are at risk for intracranial hypertension
- Monitoring ICP is useful in critically ill patients to manage intracranial hypertension, to guide ICP-targeted therapies, to calculate and monitor cerebral perfusion pressure, and to drain CSF.
- Intraventricular and intraparenchymal probes are equally effective in measuring ICP. Ventriculostomy must be continuously zeroed. Fiberoptic monitors are zeroed before insertion and are not affected by the patient position or bed height. The drift of measurements over time can be a problem, and intraparenchymal probes do not allow CSF drainage. ICP can also be measured via subarachnoid, epidural/subdural, or lumbar drains. Compared to intraventricular or intraparenchymal catheters, subarachnoid and subdural/epidural probes do not guarantee a reliable measure of ICP.
- The risk of hemorrhagic complications from the placement of an ICP monitor ranges from approximately 0.5% to 10%. The risk of a hemorrhage increases dramatically when coagulation abnormalities are present. The placement of intraparenchymal probes is easier than with intraventricular catheters, particularly in conditions of brain edema and ventricular effacement.
- The rate of infection associated with ICP monitors correlates with duration of placement, presence of a CSF leak, the frequency of CSF sampling, presence of intraventricular hemorrhage, and concurrent systemic infection. The utility of prophylactic antibiotics and daily surveillance of CSF cultures is highly controversial. The rate of catheter-related infection is lower with intraparenchymal than intraventricular catheters.

■ BEFORE PROCEDURE

Indications

- A need for estimating energy expenditure (EE) in critically ill patients in whom the EE is highly variable and difficult to predict by simple equations, such as
 - Patients with liver disease
 - Obese patients

Contraindications

- Absolute contraindications
 - Situations preventing a complete collection of expired gases
 - Leaks of gas from the ventilator circuit
 - Leaks around endotracheal tubes
 - Leaks through chest tubes
 - Instability of delivered oxygen concentration
 - Oxygen concentration above 65
- Relative contraindications
 - Ongoing hemodialysis
 - Hemodynamically unstable patient
 - Large bias flow
 - Extreme circuit flow rates

Equipment

- Indirect calorimeter

■ PROCEDURE

See Video E21-1.

- Select the patient.
- Connect the inspiratory sampling line tube to the water trap container.

- Switch on the monitor.
- Warm up for 30 minutes.
- Choose the correct respiratory mode.
- Perform gas calibration.
- Insert patient data.
- Connect the mixing chamber inlet to the expiratory outlet of the respirator.
- Place the inspiratory sampling line in the inspiratory tube of the respirator.
- Press start.
- Measure for at least 30 minutes.
- Get a report.

■ AFTER PROCEDURE

- Adjust metabolic care according to the metabolic measurements.

Complications

- Common
 - Inaccurate measurements due to equipment malfunction and methodologic problems
- Infrequent
 - Infections cross over.

■ BEFORE PROCEDURE

Indications

- Venovenous extracorporeal membrane oxygenation (ECMO)
 - Inability to oxygenate and/or ventilate a patient due to the following
 - ARDS
 - Pneumonia
 - Lung Transplantation (Primary Graft Dysfunction)
 - Reperfusion ischemic injury
 - Rejection
 - Infection
 - Technical issues
 - Bridge to lung transplantation
 - Failure to achieve adequate PaO_2 (>50) on 100% FiO_2 or persistent shunt >25% despite an optimally tolerated PEEP through the following therapies
 - Failed trial of pressure control/inverse ratio
 - Trial of diuresis
 - Trial of paralytics
 - Trial of nitric oxide
 - Trial of high frequency of oscillator ventilation
 - Consider trial of prone positioning
- Venoarterial ECMO
 - Indication for ECMO in adult cardiac failure is cardiogenic shock: Inadequate tissue perfusion manifests as hypotension and low cardiac output despite adequate intravascular volume
 - Typical causes
 - Acute myocardial infarction
 - Myocarditis
 - Peripartum cardiomyopathy
 - Decompensated chronic heart failure
 - Postcardiotomy shock
 - Heart transplantation (primary graft dysfunction)
 - Ischemic reperfusion injury
 - Rejection
 - Pulmonary hypertension
 - Technique issues
 - Bridge to heart or heart-lung transplantation
 - Shock persists despite the following therapies
 - Volume administration
 - Inotropes and vasoconstrictors
 - Mechanical support with intraaortic balloon counterpulsation or impella if appropriate

Contraindications

- Absolute contraindications
 - Age greater than 65
- Significant life-limiting disease
 - Significant baseline lung disease including home O_2 dependence or heart disease
 - Not a transplant candidate
 - Encephalopathy
 - Cancer

- Cirrhosis
- HIV
- Recent stroke/intracranial hemorrhage
- Suspicion of anoxic brain injury
- Relative contraindications
 - Bleeding diathesis
 - Gastrointestinal bleed
 - Greater than 14 days of mechanical ventilation
 - Encephalopathy

Equipment

- Permanent equipment
 - 1—Centrifugal pump
 - Maquet Cardiohelp
 - Integrated pump and oxygenator
 - Provides real-time arterial and venous pressures, hemoglobin and SVO_2
 - Thoratec Centrimag
 - Magnetically levitated pump impella—contract free for less hemolysis
 - 1—ECMO cart (including instrument tray)
 - 1—Oxygenator bracket (Quadrox D)
 - 1—Pump external drive
 - 1—Heater/cooler with appropriate water lines and connectors (BioCal or Sarns) or heating blanket
 - 1—Oxygen/medical air blender with appropriate length (20 ft each) gas lines and connectors for all operating rooms and intensive care areas
 - 1—Cardiotomy reservoir holder
 - 1—Manifold for pressure readings on the BioPump 540 transducer, Medtronic DLP pressure display
 - 6—Tubing clamps and scissors
 - 1—Hand crank
 - 1—Bed plate with two long poles
 - 1—Blue roller clamp assembly for recirculation line (10 mm Keck roller clamp from Cole Parmer)
 - 2—Full 100% oxygen E cylinders with a tubing adaptor
 - 1—Set of each: four types of gas connectors
- Possible accessory equipment
 - 1—Hemoconcentrator bracket
- Disposable supplies
 - ECMO CARMEDA-bonded (CB) Medtronic custom tubing pack or a Maquet custom tubing pack—Quadrox Bioline or Levitronix pump head
 - Cardiotomy reservoir
 - Walrus extension connectors with high-flow stopcocks
 - Terumo extensions high flow (one positive and one negative for kidney)
 - Pressure veil and isolator tubings or DLP pressure display set
 - 3/16" to male connectors
 - Extra 3/8" CB straight connectors with a Luer-Lok
 - 3/8" non-Carmeda bonded connector
 - 3/8" perfusion adaptor
 - Plasmalyte-A pH 7.4—2000 mL (prime the circuit)
 - Sterile water for irrigation for BioCal or Sarns water heater (approximately 3 to 4 L)

- Syringes; 3 mL, 10 mL, and 60 mL
- Blood filter
- Extra supplies for ECMO site
 - CB BioMedicus cannulae
 - 50-cm venous: 29F; 27F; 25F;
 - 18-cm arterial: 23F (for venous insertion), 21F, 19F, 17F, and 15F
 - CB Medtronic DLP malleable venous cannulae: 32F, 36F, and 40F
 - CB EOPA cannulae: 20F; 22F; 24F
 - CB/non-CB right angle venous: 40F
 - CB Edwards RMI 36F RA
 - CB two-stage 36/46
- Avalon cannula (double lumen cannula): 23F, 27F, and 31F
- Insertion kits for cannulae (RMI PIKV for 23, 25, 27, and 29 venous)
- Extra oxygenator Quadrox D
- Fresenius hemoconcentration (with Terumo tubing assembly)
- SCUF custom tubing pack
- IV tubing for hemofiltration
- Extra CB VAD/liver pack
- Extra length CB 6-ft. $3/8" \times 3/32"$ tubing (sterile) and $1/4 \times 3/32"$ sterile tubing
- CB $3/8"$ connectors with Luer-Lok
- 8F pediatric arterial CB cannula with $1/4" \times 3/8"$ connector and $1/4"$ tubing CB (for distal femoral artery perfusion)
- Walrus large-bore stopcock and extension assemblies
- Terumo high-flow extension stopcocks
- Isolator (pressure veils), $3/16"$ male connectors, and stopcocks
- 3-mL, 10-mL, and 60-mL syringes
- 18-gauge needles and sterile safety blades or sterile scissors
- Plasmalyte-A pH 7.4
- Blood filter (40 microns)
- Heparin (1:1000 units/mL)
- 210-cm guide wire
- 100-cm guide wire
- Small biohazard bags
- Panduit ties and gun
- Appropriate charts, ECMO pre-bypass checklist, ECMO shift schedule, and a shift checklist

ANATOMY

For femoral cannulation should locate the femoral triangle of the patient. The femoral triangle is the name given to an area of the anterior aspect of the thigh formed as different muscles and ligaments cross each other producing an inverted triangular shape. Contained within this area, placed medially to laterally, are the femoral vein, artery, and nerve (remember "van"). The borders of the triangle are composed of the medial border of the sartorius that forms the lateral border of the triangle, while the inguinal ligament forms the superior border, and the medial border is formed by the medial border of the adductor longus. Within the triangle, the femoral artery lies at the midinguinal point, which is the midway point between the pubic symphysis and the anterior iliac spine. This midway point is an important landmark in locating the femoral artery. It is also an important landmark within the leg since medial to the femoral artery is the femoral vein. Thus, in effect, you can locate the femoral vein by palpating the femoral pulse and moving your needle medially.

The internal jugular vein lies within the triangle that is made up by the lateral head of the sternocleidomastoid muscle, medial head of the sternocleidomastoid muscle, and the clavicle inferiorly. Locate the apex of the triangle, and move inferiorly to the center to locate the internal jugular vein. The apex of this triangle is a good landmark in locating the internal jugular vein. The carotid artery lies lateral and inferior to the internal jugular vein.

In the anatomy for central ECMO cannulation, the ascending aorta located within the mediastinum is cannulated with the arterial

cannula, and the right atrium is cannulated with the venous cannula in venoarterial ECMO. In central venovenous ECMO, cannulas are placed in the right atrium (venous cannula) and pulmonary artery (arterial cannula).

PROCEDURE

• Venovenous percutaneous

Cannulation is usually performed at the patient's bedside with the assistance of nursing staff. Percutaneous venous cannulation for ECMO is achieved with the use of a modified Seldinger technique. The right neck and the appropriate groin region are prepared and draped in a sterile fashion, and anesthesia is achieved with a local anesthetic. Unless contraindicated by immediate postoperative status, all patients receive a bolus of 3000-5000 units of heparin (or 100 units/kg) for the cannulation procedure (percutaneous or open). The vein (e.g., femoral or jugular) is accessed at an angle of approximately 30 degrees with the skin, and the guide wire is passed through the needle. As for any percutaneous technique, the guide wire should pass unimpeded. Occasionally, the onset of cardiac ectopy provides evidence regarding the location of the wire's tip. We commonly temporarily replace the wire with an Angiocath or small dilator to verify that the access achieved is venous and not arterial. The wire is then replaced, and, using it as a guide, sequentially larger dilators are passed. Manual compression of the insertion site is used to prevent excessive bleeding as the dilators are sequentially removed and reinserted. It is very important to ensure that the wire moves freely during dilatation as well as cannula insertion. Free movement of the guide wire indicates that the dilator or cannula is following the path of the wire and not kinking and taking an alternative path, such as through the vessel wall. Kinking can be prevented by gentle traction on the wire applied by an assistant as the dilator or cannula is passed. Creation of a skin incision slightly smaller than the cannula being inserted facilitates passage of the cannula while still providing good hemostasis. Occasionally, difficulty is encountered with the passage of the cannula under the inguinal ligament or through the dilated opening in the vessel wall. Redilatation with a smaller dilator can facilitate passage. The preferred drainage site is the femoral vein, and the cannula is advanced to just below the caval-atrial junction. The flows are usually the maximum capable with consideration to negative inlet pressures, RPMs, and positive resistance. Inflow to the patient is usually the right internal jugular vein, using a CB arterial BioMedicus cannula (usually 17F, 19F, or 21F CB BioMedicus).

If a secondary site is needed, the femoral and internal jugular may be used and "Y'd" to the venous tubing for venoarterial ECMO.

The Avalon cannula can be inserted into the IJ using the 23F, 27F, or 31F. This cannula allows drainage from the cannula holes sitting in the IVC and SVC and return blood to the RA. A baffle in the cannula separates inflow from outflow.

After cannulation, it is important to assess the cannula position by obtaining a radiograph.

• Venoarterial percutaneous

See Video E22-1.

The preferred site is the femoral artery. Surgical (as well as percutaneous) insertion of arterial cannulas in the femoral artery can be complicated by malperfusion of the distal extremity. This complication may be addressed in several fashions but should be dealt with expeditiously to avoid severe injury. We prefer the insertion of a modified, cut high-pressure monitoring line (arterial line tubing) down the femoral artery of the affected limb. This can be achieved in the open wound just distal to the reinfusion cannula insertion site or, in the case of a percutaneous cannula, via an incision at a separate site. The tubing is connected to a CB $3/8 \times 3/8$ -inch connector with a Luer-Lok between the arterial cannula and the ECMO arterial pump tubing. If decreased heparinization and low flow in this system are concerns, heparin of 0.5 to 2 U/kg/hr may be infused by a pressure pump into this system for anticoagulation.

• Venovenous/venoarterial surgical cut-down

Using the same cannulas, when there is difficulty with percutaneous cannulation or the body habitus is not conducive surgical cut-down to gain access to the femoral vessels can be done either at the bedside or if time allows in the operating room cannulation.

- Central cannulation

ECMO may be performed with central cannulation with a CB Medtronic 35 cm DLP 32F, 36F, or 40F malleable venous, CB Medtronic DLP 2 stage 34/46, and DII 40F RA for right or left atrial cannulation. Inflow to the patient may be accomplished with Carmeda EOPA 22F or 24F or other appropriately coated cannula for a PA or aorta. The median sternotomy is the least favored as this site is associated with more bleeding complications. The cannulae may be tunneled inferior to the sternum and the chest then closed for hemostasis.

AFTER PROCEDURE

Postprocedure Care

- Daily patient and circuit management on ECMO including
 - Patient
 - Fluid
 - Electrolytes
 - Nutrition
 - Respiratory
 - Neurologic
 - Infection control
 - Sedation and pain control
 - Hematology
 - Cardiac
 - Psychosocial
 - Circuit
 - Aseptic technique
 - Pump/gas flow pressure monitoring
 - Blood product infusion techniques
 - Circuit infusions
 - Management of anticoagulation
 - Circuit checks
 - Hemofiltrations setup
 - Bedside care of the ECMO patient
- Weaning from venovenous ECMO is done by turning off the gases after placing the patient on reasonable ventilator settings and closely monitoring arterial saturations. The patient is decannulated after being maintained off of gases for 24 hours.
- Trial or wean with a VA system is very different. The arteriovenous bridge is used. The ventilator is set at the optimal setting. Additional heparin is given to achieve an ACT of 300 seconds. ECMO flows may be reduced by 1 L/min at intervals, and observations of the patient's hemodynamics and arterial saturation are critical. Echocardiogram imaging is also useful in determining when the patient may be ready to be cannulated.

Complications

- Medical
 - Intracranial and another hemorrhage
 - Pneumothorax/pneumopericardium
 - Cardiac arrest
 - Hypotension/hypovolemia
 - Severe coagulopathy/thrombocytopenia
 - Seizures
 - Hemothorax/hemopericardium
 - Uncontrolled bleeding
- Mechanical
 - Circuit disruption
 - System or component alarm/failure (e.g., pump, bladder, venous return monitor oxygenator, or heater)
 - Air embolus
 - Inadvertent decannulation
 - Clots

OUTCOMES AND EVIDENCE

- Patient outcomes after ECMO cannulation are very much dependent on the coexisting condition at the time of cannulation, as well as the clinical state of the patient on ECMO support.
 - Comorbidities precannulation
 - Organ dysfunction
 - Length of cannulation
 - Type of ECMO support
 - Venovenous vs. venoarterial
- Outcomes trial
 - CESAR trial
 - Of patients assigned to consideration for treatment by ECMO, 63% (57/90) survived to 6 months without disability vs. 47% (41/87) of those assigned to conventional management (relative risk: 0.69; 95% confidence interval [CI]: 0.05-0.97; $P = 0.03$).
 - ECMO in influenza H1N1 epidemic
 - The median duration of ECMO support was 10 (7-15) days. At the time of reporting, 48 of the 68 patients (71%; 95% CI: 60%-82%) had survived to ICU discharge, of whom 32 had survived to hospital discharge and 16 remained as hospital inpatients. Fourteen patients (21%; 95% CI: 11%-30%) had died, and six remained in the ICU, two of whom were still receiving ECMO.
 - Survival outcomes following the use of ECMO in patients with acute respiratory failure during the H1N1 influenza pandemic have validated the role of ECMO as an important management strategy in adults with severe respiratory failure.
- There is a lack of quality RCTs of ECMO outcomes in the adult population, especially venoarterial ECMO.

Laparoscopy has proven itself an accurate diagnostic tool in a wide spectrum of clinical scenarios. More recently, it has been applied in the evaluation of both trauma and intensive care unit (ICU) patients. This chapter will focus on diagnostic laparoscopy for the critically ill patient in the ICU.

Acute intraabdominal pathologies remain a significant source of morbidity and mortality in the ICU. Etiologies include acalculous cholecystitis, intestinal ischemia, intestinal perforation, peptic ulcer disease complications, pseudomembranous colitis, diverticulitis, and pancreatitis, to name a few. Specifically, acalculous cholecystitis has been documented in 1% of surgical ICU patients and 0.5% of critically injured trauma patients. Likewise, intestinal ischemia is a significant risk following aortic procedures.

While those above occur relatively infrequently, associated morbidity and mortality are significant. If left undiagnosed and/or untreated, intraabdominal sepsis may lead to multiple organ failure (MOF), with mortality rates approaching 100%. The reported mortality rates specific to acalculous cholecystitis and mesenteric ischemia range from 50% to 100%.

A significant contributor to the high morbidity and mortality rates is a delay in diagnosis. Such delays are multifactorial and include failure to consider the diagnosis, difficulty in obtaining the diagnosis secondary to patient safety issues, and the lack of accuracy of the diagnostic modalities.

Critically ill patients also have numerous other potential sources of sepsis, further complicating the picture (e.g., central venous catheter infection, ventilator-associated pneumonia, and a urinary tract infection). As such, surgical consultations are often sought in these patients; indications include abdominal pain, abdominal distention, a fever of unknown etiology, sepsis of unknown etiology, inexplicable acidosis, enteral intolerance, and others. This often presents a diagnostic dilemma. Diagnostic modalities to assess the abdomen in this critically ill population include the physical examination, laboratory studies, plain radiography, computed tomography (CT) scans, ultrasound, diagnostic peritoneal lavage (DPL), exploratory laparotomy, and increasingly, diagnostic laparoscopy.

■ BEFORE PROCEDURE

Indications

Critical illness with suspicion for intraabdominal pathology with

- Inability to perform an exam (unreliable physical exam findings)
 - Altered mental status
 - Sedation
 - Paralysis
- Inability to transport for diagnostic radiologic imaging
 - Hemodynamic instability
 - Pulmonary instability
- Inability to make a diagnosis with given information
 - For example, radiologic imaging is equivocal or nondiagnostic
 - Other modalities unlikely to provide a diagnosis
 - For example, DPL is unable to diagnose a diaphragm injury

Contraindications

- Intraabdominal hypertension
- Open abdomen

- Recent abdominal wound dehiscence
- Previous laparotomy (relative contraindication)
- Recent laparotomy is not an absolute contraindication
- Hemodynamic instability (relative contraindication)

Equipment

- ICU equipment
- Monitoring
 - Continuous monitoring
 - Electrocardiogram (ECG)
 - SpO₂
 - Noninvasive blood pressure (NIBP) or arterial line
 - If NIBP record at least once every 3 minutes
 - End-tidal carbon dioxide (CO₂) monitor
 - Bispectral index (BIS) monitoring during administration of anesthesia (optional)
- Ventilator
 - Full ventilatory support may or may not be required based on patient condition.
 - If the patient is not intubated, the team should be fully prepared for endotracheal intubation.
- Laparoscopic equipment
 - Mobile laparoscopic cart with locking brakes and four antistatic rollers
- Optical equipment
 - Laparoscopic camera system
 - Laparoscopic light source
 - Video monitor
 - Only one monitor is necessary.
 - Ideally, the monitor should be able to tilt, swivel, and pivot on a boom.
 - A second monitor can be “slaved” from the main monitor and positioned for the assistant to see.
 - Video recorder (optional)
- Laparoscopic CO₂ insufflator system with a pressure monitor
- CO₂ gas tank with a backup tank and wrench tool
- Monopolar electrocautery generator with grounding pad
- Laparoscopic-specific set (sterilized)
 - Fiberoptic light cable
 - Telescopes
 - 10-mm scope (0- and 30-degree angles)
 - 5-mm scope (0- and 30-degree angles)
 - CO₂ insufflation hoses with a filter
 - Trocars/ports (surgeon specific)
- Entry technique
 - Open (Hasson method)
 - 12-mm Hasson port
 - Optiview visualizing trocar
 - 5-mm clear
 - Blind
 - Veress needle
 - 5- to 12-mm trocar
- Additional ports
 - Additional ports dictated by surgeon requirements
- Laparoscopic instruments (minimal necessary)
 - Ratcheted atraumatic graspers (×2)
 - Nonratcheted atraumatic graspers (×2)

- Maryland dissector
- Laparoscopic scissors
- Cauterization instrumentation with associated generators
 - Monopolar system
 - Other 5-mm cauterization systems can be used if necessary, such as
 - Harmonic
 - Ligasure
 - EnSeal
- Laparoscopic suction-irrigator
- Basic abdominal surgical set
 - Surgical sterile prep system
 - Laparotomy towels and drapes
 - Laparotomy sponges
 - Scalpel (#11 blade and/or #15 blade)
 - Suture
 - 0-polyglactin 910 suture on UR-6 needle (×2)
 - 4-0 polyglecaprone 25 suture on PS-2 needle (×2)
 - Surgical pickups
 - Adson tissue forceps (×2)
 - Rat-toothed, heavy forceps (×1)
 - Suture scissors
- Dressings
 - ¼-inch Steri-Strips
 - Surgical wound covers
 - Band-aids *or*
 - 2 × 2 sterile gauze with clear occlusive dressing

ANATOMY

Special considerations for patient selection and the entry technique need to be evaluated. Prior operations may preclude the ability to enter the abdomen safely or may obscure the clinician's ability to perform a complete visual inspection of its contents because of adhesive disease. In these cases, diagnostic laparoscopy may not be successful. Patients with portal hypertension are at an increased risk of bleeding due to the inadvertent injury of dilated venous collaterals that are not normally present within the abdominal wall. Finally, the inferior epigastric artery is at risk for injury during trocar placement, and careful attention should be paid to avoid its consistent location within the rectus sheath.

PROCEDURE

- The procedure can be performed safely with the following personnel
 - The surgeon (laparoscopist)
 - The intensivist/anesthesiologist for administration of sedation and analgesia, as well as for respiratory and hemodynamic monitoring
 - A scrub nurse to assist the surgeon
 - An ICU nurse (circulator) to obtain necessary equipment and medications
 - A respiratory therapist on standby to assist the intensivist/anesthesiologist
- The patient's position is neutral and supine.
- Complete prep and drape in standard fashion
- Monitoring should be continuous or at least every 3 minutes and include
 - Blood pressure, pulse rate, respiratory rate, tidal volume and peak inspiratory pressure, oxygen saturation (SpO₂), and end-tidal PCO₂
 - A bispectral index (BIS) monitor is optional.
- Sedation and analgesia provided intravenously
 - A narcotic (e.g., fentanyl, morphine)
 - A sedative
 - Benzodiazepines (e.g., midazolam, lorazepam)
 - Propofol
 - A paralytic (e.g., vecuronium, rocuronium, or cisatracurium)

- Diagnostic laparoscopy has been done successfully using only local anesthesia and a mild sedative.
 - For complex ICU patients with suspected intraabdominal pathology, using local anesthesia is not optimal.
- Decompression of the stomach with a nasogastric tube (NGT) and the bladder with a Foley catheter is advisable.
- A vertical incision is placed just cephalad or caudad to the umbilicus.
- This can be extended if a formal laparotomy is necessary.
- Open approach
 - Under direct vision, the fascia and peritoneum are opened through the linea alba.
 - Stay sutures (0-polyglactin 910) are placed (can be used to close fascia at the end of procedure).
 - The cannula is inserted, and the two facial sutures are looped around it in the provided grooves for stabilization.
- Blind techniques can be used if deemed safe and can minimize the incision necessary for peritoneal access.
- CO₂ is insufflated slowly to minimize adverse effects on respiratory function and hemodynamics.
- Some advocate lower insufflation pressures (8-12 mm Hg). No studies have been performed comparing different insufflation pressures.
- Angled scope is preferred for improved visualization.
- If the procedure is performed for a trauma patient, inspection of the diaphragm should be the first step (to reduce risk of tension pneumothorax if diaphragm injury).
- A quick inspection around the abdominal cavity for any obvious signs of peritonitis. If found, terminate the procedure and prepare for the formal therapeutic operation.
- Additional 5-mm ports can be placed under direct vision as necessary.
- Complete the inspection as you would with formal exploration, in an organized fashion, including all abdominal and pelvic viscera in addition to peritoneal surfaces.

AFTER PROCEDURE

Postprocedure Care

- Continuous monitoring with ECG, SpO₂ and NIBP as long as patient condition warrants
- Maintain NGT to suction and Foley to gravity.
- Check the arterial blood gas (ABG) for acidosis and hypoxemia.
- Optimize ventilation and oxygenation.
- If the laparoscopy was nondiagnostic, the surgeon should be prepared to perform a laparotomy, either at bedside if patient condition warrants or in the operating room if the patient is stable for transport.

Complications

- Common
 - Increased intraabdominal pressure, which may result in
 - Oliguria
 - Increased peak airway pressures and resistance
 - Decreased functional residual capacity and lung compliance
 - Increased difficulty with ventilation and/or oxygenation
 - Hypotension due to
 - Decreased venous return and/or increased systemic vascular resistance (afterload)
 - Hypercarbia with associated metabolic acidosis
 - Results from increased pulmonary dead-space and peritoneal absorption of insufflated CO₂
 - Usually transient
 - Can be corrected through increasing minute ventilation

- Infrequent
 - Intestinal injury due to
 - Trocar insertion
 - Manipulation of bowel or intestinal adhesiolysis
 - Use of electrocautery
 - Vascular injury due to
 - Trocar insertion
 - Manipulation of mesentery
 - Bladder injury due to
 - Trocar insertion
 - Deep venous thrombosis
 - Associated with prolonged procedures coupled with prolonged impaired venous blood return and perioperative hypercoagulability
- Serious, rare complications
 - Gas embolization from CO₂ pneumoperitoneum into the venous system, manifested by
 - Sudden hemodynamic collapse with precipitous drop in end-tidal CO₂ (not specific)
 - Positioning patient in steep Trendelenburg and rolled to the left may put gas embolism away from pulmonary outflow tract and restore blood flow out of the right heart.
 - Tension pneumothorax due to CO₂ tracking through gaps in the diaphragm into the pleural space
 - Acute volume overload and pulmonary edema
 - Can result after the release of pneumoperitoneum
 - Large amounts of intravenous fluids infused during the procedure to maintain a hemodynamic status
 - Elevated intracranial pressure (ICP)
 - Hypercarbia can result in cerebral vasodilation, with the concomitant potential for increased ICP.
 - Intraabdominal hypertension can impede venous flow from the periphery and increases the cerebrospinal fluid pressure.
 - Despite the significant advantages of laparoscopy, it is not without its disadvantages. The most concerning are potential

detrimental physiological effects, specifically to the cardiovascular and pulmonary systems. Experimental animal models demonstrate hemodynamic compromise in septic animals undergoing laparoscopy, usually secondary to the associated hypercarbia and acidosis. Others document temporary myocardial insufficiency, with decreases in cardiac output up to 80% after only 20 minutes of CO₂ insufflation. However, many studies report no hemodynamic alterations during laparoscopy. Means of avoiding such outcomes include slow CO₂ insufflation, lower intraabdominal pressures, using alternative gases for insufflation (e.g., nitrous oxide), and ultimately, desufflation if necessary.

OUTCOMES AND EVIDENCE

- Bedside laparoscopy in the ICU is safe and effective in diagnosing intraabdominal pathology in critically ill patients.
- Gagné et al. performed 20 bedside laparoscopic procedures on 19 patients, with a mean time of 21 minutes; 18 of 19 patients avoided nontherapeutic laparotomy as a result.
- Pecoraro et al. reported that 4 of the 11 patients had recent laparotomies. In 6 of the 11 patients studied, the use of bedside laparoscopy avoided nontherapeutic open laparotomy.
- Kelly et al. performed 17 cases, 16 completed. No complications, with 100% accuracy among the 16 completed procedures. Abdominal CT in 9 patients was accurate in only 33%.
- Hackert et al. studied 17 patients, revealing a 94% sensitivity for bedside laparoscopy.
- Peris et al. performed the largest (retrospective) study to date with 32 patients, a mean time of 40 minutes, and no complications; 15 (46.9%) of the patients had a pathologic finding necessitating intervention; 6 patients with sepsis, who had prior negative diagnostic peritoneal lavages, were found to have peritonitis via a diagnostic laparoscopy.

■ INTUBATION: BEFORE PROCEDURE

Indications

- Airway patency
 - Anatomic obstruction
 - Congenital anomalies
 - Acquired obstruction
 - Infectious obstruction
 - Inability to functionally maintain airway (e.g., depressed level of consciousness)
 - Loss of airway cough and/or gag reflex
 - Neuromuscular weakness
- Lower respiratory failure
 - Inability to ventilate/exchange PCO_2
 - Inability to oxygenate
 - Relieve increased work of breathing
 - Neuromuscular weakness
 - Need for aggressive pulmonary toilet
- Hemodynamic instability
- Need for controlled ventilation
 - Pulmonary hypertension
 - Intracranial hypertension

Contraindications

- In emergent situations, there is no contraindication for endotracheal intubation.
- Relative contraindications
 - Abnormal anatomy; may require an alternative approach to airway management (e.g., cricothyrotomy with retrograde intubation or bronchoscopic intubation)
 - Profuse upper airway or lower airway bleeding
 - Increased intracranial pressure (ICP): requires rapid-sequence intubation
 - Cervical or suspected cervical spine injury: requires immobilization of the head and neck

Equipment

- Monitoring equipment: pulse oximeter, electrocardiogram (ECG), blood pressure
- Oxygen source: delivered by mask before intubation; if apneic, oxygenation to be used and then high-flow nasal cannula
- Bag for manual ventilation
 - Anesthesia-type bag: expands when connected to gas flow; various designs available but must have adequate flow through system to prevent rebreathing
 - Self-inflating bag: designs vary; many have pressure pop-off at 35 to 45 cm H_2O , so if lungs are severely noncompliant, may not adequately ventilate or oxygenate with this bag or may need to bypass the pop-off
- Laryngoscope
 - Check before use for adequate battery and bulb function.
 - Small handle and larger handle are available.
 - Bronchoscopic and video laryngoscopes are available.

- Laryngoscope blade
 - Various sizes and styles are available.
 - Size must be appropriate for child
 - Too short will not visualize the larynx.
 - Too long may apply too much pressure and take too much room in the mouth.
 - Width is also important
 - Wide blades will help manage the tongue, which can be disproportionately large in children.
- Endotracheal tubes (ETTs)
 - Appropriate estimated size tube: $(\text{Age} + 16)/4 = \text{Endotracheal tube size}$
 - Adjust for extremes in patient size or known abnormality of tracheal size.
 - Tubes are cuffed and uncuffed
 - Cuffed tubes are universally recommended above age 8 years.
 - Under age 8 years, most recent recommendations are that cuffed tubes may be used. In the past, cuffed tubes were thought to be unnecessary because of the narrow trachea at the level of the cricoid cartilage and potentially risky because of the risk of airway injury. Currently, the cuffs are high-volume, low-pressure cuffs that require lower pressure to be effective, therefore decreasing the risk of airway injury. For patients with noncompliant lungs requiring higher airway pressures, the presence of a cuff decreases the air leak, allowing for better lung inflation and recruitment. The cuff may not need to be inflated to adequately manage air leakage, thus decreasing the risk of airway injury.
 - Stylets: available in pediatric and adult sizes; may be needed to help strengthen the pliable ETT to assist in intubation; skill and experience of the operator will dictate its usefulness.
- Suction devices: must be sturdy enough to suction very thick secretions in even the smallest infant
- End-tidal CO_2 detector: disposable colorimetric CO_2 detectors are available in pediatric and adult sizes; the weight of the patient will determine the size of the device.
- Means for securing the ETT: either tape or an appropriately sized securement device
- Airway support devices: these may be useful depending on the stability of the airway
 - Oral airways: come in various sizes; poorly tolerated in a conscious patient; may be needed for airway maintenance before intubation
 - Nasopharyngeal airways: come in various sizes and can relieve nasal and pharyngeal obstruction in conscious patients, including children. The appropriate-sized airway extends from the nares to the tragus of the ear. The diameter should be large enough that it does not cause obstruction and not so large that it causes blanching of the alae nasi, which can lead to necrosis.
 - Laryngeal mask airway: can provide immediate airway access and should be available during even nonemergent intubation in the event the airway is difficult to intubate. They come in a variety of sizes appropriate for pediatric patients. The LMA consists of a wide-bore tube with a standard 15-mm adapter at

the proximal end for attachment to the circuit or resuscitation bag. The distal end is an elliptical mask that can be inflated and conforms to the shape of the larynx, providing a low-pressure seal for ventilation at the level of the larynx (see [Procedure](#)).

- Pharmacologic agents: various sedative and paralytic drugs are available for intubation. There are different conditions for intubation that require certain combinations of drugs for safest and most effective intubation. One must be familiar with the variety of drugs available, including side effects, indications, and contraindications.
 - Anticholinergic agents: prevent bradycardia during laryngoscopy and decrease oral secretions
 - Sedative agents: in choosing one of these agents, consideration should be given to hemodynamic status, the presence of increased ICP, age of patient, underlying chronic medical conditions, and the current disease process
 - Anxiolytics including benzodiazepines (e.g., midazolam or lorazepam)
 - Narcotics including opiates (e.g., fentanyl or morphine)
 - Anesthetics (e.g., ketamine, etomidate, or propofol)
 - Neuromuscular blockers
 - Nondepolarizing agents
 - Amino-steroid agents: vecuronium or rocuronium
 - Benzylquinolinium agents: atracurium or cisatracurium
 - Depolarizing agents: succinylcholine; there is a U.S. Food and Drug Administration (FDA) warning against its routine use in children because of the frequency and severity of side effects. Although its rapid onset of action in emergencies is thought to be useful, the onset of action is not significantly advantageous over rocuronium, which has fewer side effects.

■ ANATOMY

The pediatric airway changes with age and development and differs from the adult airway in many aspects. Understanding these differences and being aware of the age-related changes are important for optimal airway management. The larynx in children is located higher in the neck, with the epiglottis being at the level of C1 as a neonate and at the level of C3-4 by 6 months of age, as opposed to the adult, where the larynx is around C5. This more superior position of the larynx creates more acute angulation during laryngoscopy and can make the visualization of the glottic opening more difficult. Also, the tongue is located more superiorly and closer to the palate in children than in adults and is larger in relation to the bony structures of the cranium, potentially causing airway obstruction. The narrowest portion of a child's airway is the subglottic region, whereas the narrowest portion of an adult airway is the vocal cords. This difference has allowed for uncuffed tracheal tubes to be used in infants and young children. Another major difference is that children have a more protuberant occiput, which may cause excessive neck flexion. Finally, the infant's nares are smaller. Since infants are obligate nasal breathers for the first 6 months of life, occlusion of the nasal passages with secretions, edema, or blood can cause significant resistance to airflow and significantly increase the work of breathing.

■ BEFORE PROCEDURE

If time allows and the procedure is not emergent, then a preprocedure plan should be in place. A plan should include assessing the airway, risk for hypotension or hypoxemia during the procedure, and the risk of hypercarbia (is there increased intracranial pressure or pulmonary hypertension). A plan should include who is most appropriate to do the intubation (i.e., what skill level would be needed), for instance, a pediatric ICU fellow, PICU attending, anesthesiologist, or even ENT surgeon. The method of intubation should be discussed, including which medications would be appropriate and the indications for

intubation. A backup plan for airway support if the airway proves to be difficult should be conceived and in place.

■ PROCEDURE

- Evaluate the difficulty of airway intubation and risk for complications.
 - History of difficult airway
 - Physical examination with attention to size of mouth, size of tongue, small mandible, large head
 - Potential for hypoxemia or hypotension during procedure
 - Need to avoid hypercarbia via pulmonary hypertension, increased intracranial pressure
- Secure equipment and test functionality
 - Test patency of intravenous (IV) access.
 - Check bag and mask for adequate oxygen flow.
 - Check suction device for adequate suction.
 - Check laryngoscope handle and blade for the presence of bright light.
 - For cuffed ETT, check cuff for the ability to hold air.
 - Place stylet in ETT if desired.
 - Have ETT one size larger and smaller available.
- Have proper personnel available including nursing, respiratory therapy, and more experienced intubators if appropriate.
- Monitor the patient with pulse oximeter, ECG, blood pressure cuff (set to cycle frequently during procedure).
- Preoxygenate patient; if possible allow the patient to breathe spontaneously on FiO_2 1.0 or as much as can be delivered to maximally increase the patient's PaO_2 prior to the intubation attempt; apneic oxygenation using high-flow nasal cannula providing continuous oxygen flow even after paralytics are given may be helpful in preventing desaturation during intubation.
- Position the patient's head; the goal of head positioning is to align the oral, pharyngeal, and laryngeal axes.
 - Infants have a large occiput that puts them close to proper alignment, although they may need a roll under the shoulders; care should be taken to avoid overextension of the head, which also misaligns the airway.
 - Children should have a roll under the occiput to put the head in a "sniffing" position, which will better align the airway.
 - Head extension in both groups better aligns the airway.
- Administer pharmacologic agents.
 - Anticholinergic may be delivered first.
 - Sedatives are given next, observing closely for changes in respiration and hemodynamics; may need to have the airway and breathing supported just with sedative administration.
 - Neuromuscular blockade is delivered last and only after determining that the airway can be managed with a bag and mask; if not, the neuromuscular blocker should not be given and intubation attempted with the patient breathing spontaneously.
- Open the mouth using the thumb and finger in a scissor-like fashion between the teeth.
- Insert the laryngoscope.
 - Hold the laryngoscope in the left hand.
 - Place it in the right side of the mouth.
 - Sweep the tongue and laryngoscope toward the left.
 - Place the tip of the laryngoscope in the vallecula or onto the epiglottis itself.
 - Visualize the larynx by lifting the mandible with the laryngoscope blade toward the ceiling at a 45- to 60-degree angle to the child's chest. Avoid "cranking" the laryngoscope back as if on a fulcrum, as this can cause injury to the lips and teeth.
 - Visualize the cords, and then place the ETT in the right corner of the mouth beside the laryngoscope blade, and advance the tube through the vocal cords. Avoid passing the tube down the laryngoscope itself, as that blocks the view of the larynx and straightens the tube, making it difficult to pass through the vocal cords.

- The tube should be advanced with the vocal cord mark just past the vocal cords to avoid right main stem intubation.

AFTER PROCEDURE

Postprocedure Care

- Immediately ensure the correct position of the ETT.
 - Place the end-tidal CO₂ detector, noting appropriate color change depending on the brand of detector. A color change should occur within six breaths unless the patient is in cardiac arrest or impending arrest.
 - Observe equal bilateral chest excursion with bag ventilation.
 - Observe maintenance of appropriate oxygen saturation.
 - Auscultate bilateral breath sounds.
- If a cuffed ETT is used, inflate the cuff with the least amount of volume necessary to prevent a leak around the ETT; overinflation of the cuff may lead to injury of the tracheal mucosa and cartilage.
- Secure the ETT using tape or a securement device.
- Confirm the ETT position with a chest radiograph.
- Suction the ETT post procedure; secretions can obstruct the tube.

Complications

- Esophageal intubation: quickly determined by lack of CO₂ detection, lack of chest wall movement, and lack of breath sounds
- Malposition of the ETT most commonly into the right main stem bronchus; common in small infants owing to the short length of their trachea; detected by asymmetric chest rising and asymmetric breath sounds. If necessary, confirm the position radiographically.
- Wrong size ETT, most commonly a too-small uncuffed tube, allowing for excessive air leakage and the inability to ventilate and oxygenate the patient; requires reintubation with proper tube size
- Undiagnosed difficult airway resulting in loss of airway during procedure or the inability to place ETT; must be managed immediately either with laryngeal mask airway (LMA) or if necessary, cricothyroidotomy; may need fiberoptic bronchoscopy to visualize the airway or may need the creation of a surgical airway
- Hemodynamic instability during the procedure due to the cardiovascular depressant effects of sedatives, hypoxemia during the procedure, or the patient's underlying disease process. May need intravascular volume expansion or even chemical resuscitation if severe enough.
- Aspiration during intubation due to a full stomach at the time of intubation; the risk is decreased if the patient is placed nil per os (NPO) for at least 6 hours prior to intubation; however, aspiration is always a risk. Aspiration in patients known not to be NPO but who need urgent or emergent intubation is decreased with emptying the stomach with a large-bore nasogastric (NG) tube and with cricoid pressure maneuver during intubation.
- Patients with increased ICP may have sharp increase in ICP during intubation, resulting in deterioration or even cerebral herniation; use rapid-sequence intubation.
 - Sedation
 - If hemodynamically unstable, etomidate or midazolam and fentanyl
 - If hemodynamically stable, midazolam and fentanyl or morphine
 - Lidocaine
 - Paralytic: rocuronium
- Patients with increased intraocular pressure may have worsening of the pressure, even resulting in extrusion of the vitreous, so rapid-sequence intubation as with increased ICP is recommended.
- Oral injuries are possible
 - Tooth injury or loss; check for loose teeth prior to intubation if time allows.

- Lacerations, bruising to lips and oropharynx
- Damage to the tonsils, including avulsion
- Damage to vocal cords and laryngeal nerve, resulting in paralytic cord(s)
- Cervical spinal cord injury in patient with unstable cervical spine; the risk is decreased when head and neck are immobilized at the time of intubation.

OUTCOMES AND EVIDENCE

- Preliminary data suggest that the use of preprocedural planning and a checklist decreases the risk of tracheal intubation-associated events.
- Successful intubation in the pediatric patient depends on the length of training, the level of supervision, the ongoing experience of the practitioner, and the use of rapid-sequence intubation.
- Cuffed ETTs are as safe as uncuffed ETTs in the pediatric patient in a prospective data collection study in a pediatric intensive care unit (PICU).
- LMA can be successfully placed in pediatric patients but may be associated with an increased risk of complications in younger patients
 - In a randomized controlled study of children 3 to 10 years of age in the operating room, both LMA and ETT were successfully placed on the first attempt in all patients, with fewer complications such as a sore throat, coughing, vomiting, and hypoxia in the LMA group.
- Patients with multiple trauma and possible cervical spinal cord injuries who were intubated emergently had no further neurologic loss following intubation, according to a retrospective study of 237 injured patients; 21 patients (8.9%) had a cervical cord or bone injury; 213 patients were orally intubated.

INTRASOSEOUS INFUSION: BEFORE PROCEDURE

Indications

- Life-threatening situations when rapid intravascular access cannot be obtained
- Cardiopulmonary arrest
- Severe shock from all causes
- Status epilepticus

Contraindications

- Bone fracture
- Previous unsuccessful attempt at that site
- Infected or burned areas; relative contraindication
- Vascular compromise to the extremity

Equipment

- Standard technique
 - Intraosseous needle
 - Needle with a stylet
 - Specially designed needles
 - Jamshidi-type needle
 - Butterfly or hypodermic needle (if that is all that is available)
 - Slip-tip syringe and tubing connector
- Powered insertion technique
 - Bone injection gun
 - Needle designed for the gun
 - Slip-tip syringe and tubing connector

ANATOMY

The preferable site for insertion is the anterior tibia, 1 to 2 cm below the tibial tuberosity on the medial aspect of the tibia. Other sites include the distal femur, medial malleolus, and anterior superior iliac spine. These sites are useful in pediatric patients from preterm neonates to adolescents. The proximal humerus is useful for adolescents and adult patients. A sternal access system is now available for adult-sized patients.

PROCEDURE

- Prepare the site using sterile technique.
- Identify landmarks.
 - Tibial tuberosity
 - Flat part of the tibia 1 cm to 2 cm below the tuberosity
- Needle entry technique
 - Standard
 - Advance the needle until a sudden decrease in resistance is felt, indicating that the bone marrow has been entered.
 - Powered insertion
 - Place the needle into powered injection gun.
 - Place the needle in the appropriate location on the patient.
 - Discharge the gun.
- Remove stylet and aspirate.
 - If the aspiration is successful, the needle should be flushed.
 - If aspiration is not successful, flush with 5 mL to 10 mL saline.
 - If it flushes easily, marrow has probably been entered.
- Attach the connector tubing, and begin infusion.

AFTER PROCEDURE

Postprocedure Care

- Careful stabilization of the intraosseous needle
- Close observation for evidence of extravasation

Complications

- Common
 - Extravasation of fluid
 - Due to the posterior penetration of the cortex
 - Due to the incomplete penetration of the cortex
 - Through a nutrient vessel foramen
 - Through a bony defect
 - Increased risk due to
 - Prolonged infusions
 - Infusions under pressure
 - Catecholamine infusions
 - Hypertonic solutions
- Infrequent
 - Compartment syndrome
 - Osteomyelitis

- Rare complications
 - Fat emboli
 - Tibial fracture

OUTCOMES AND EVIDENCE

- Intraosseous infusion
 - Easily and rapidly performed in emergency situations in both the prehospital and hospital environments
 - Effective in delivering fluids, blood, and medications in emergency situations
 - Safe but attention to the presence of infiltration or misplacement of the needle is important in preventing complications.
- Randomized controlled trial comparing standard bone marrow needle placement versus powered injector technique showed no significant difference with respect to the success rate of placement, adverse events, and time to a successful placement. Both techniques were successful about 80% of the time.

CENTRAL VENOUS CATHETERIZATION: BEFORE PROCEDURE

Indications

There are many indications for the insertion of temporary central venous catheters (CVC) in pediatric patients, and often multiple indications coexist. Since there is risk associated with both insertion and maintenance of these catheters, it is imperative that a true indication for placement be met. If more than one indication exists, the risk/benefit ratio falls in favor of catheter placement.

- Monitoring of central venous pressure (CVP) and measurement of central venous oxygen saturation (ScvO₂) in hemodynamically compromised patients
- Delivery of hypertonic or sclerosing agents
 - Total parenteral nutrition
 - Chemotherapy
 - Pressor infusions
 - Electrolyte infusions
 - Multiple blood product transfusions
 - Other medications with the risk of venous infiltration
- Poor peripheral venous access
 - Patients who need multiple IV access or long-term venous access
 - Patients needing frequent phlebotomy
- Procedures
 - Continuous renal replacement therapy
 - Hemodialysis
 - Plasmapheresis
 - Plasma exchange

Contraindications

All contraindications are relative, but the risks and benefits of the procedure must be weighed carefully.

- Coagulopathy
 - Correction of the coagulopathy should be attempted prior to the procedure if the acuity of the situation allows.
 - Sites with more risk in coagulopathic patients include subclavian and internal jugular veins; topical pressure to decrease bleeding is more effective at the femoral site.

- Skin infection at site of insertion
 - Including diaper dermatitis for femoral vein catheterization
- Site-specific contraindications
 - Avoid femoral vein catheterization in patients with abdominal catastrophes because the patency of more central veins cannot be assured.
 - Avoid internal jugular catheterization in patients with increased ICP.
 - Patients with hyperinflated lungs are at an increased risk of pneumothoraces with subclavian or internal jugular catheterization.
- Patients with active bacteremia are at risk for colonizing the CVC, so ideally the CVC would not be placed until the blood cultures are negative. That is not always possible, depending on the acuity of the patient and the patient's peripheral venous access.

Equipment

Proper insertion technique using full sterile barrier precautions and chlorhexidine prep of the skin have been shown to decrease infections associated with CVCs. Additionally, having the equipment including sterile gloves and drapes together in one location (e.g., a cart) increases the compliance with sterile technique by the insertion practitioner and makes insertion more efficient. A checklist of insertion practice also improves the compliance of proper technique.

- Sedation appropriate for age and condition of the patient with appropriate monitoring
- Local analgesia
 - 1% lidocaine with a sterile syringe and narrow-gauge needle for infiltration
 - Topical analgesia may be used prior to sterilely preparing the skin for adding analgesia.
- Sterile gloves, caps, masks, and sterile drapes
- Skin preparation antiseptic
 - 2% chlorhexidine-alcohol based skin prep is recommended.
 - Alternatives include 70% alcohol, tincture of iodine, iodophor.
- Central venous catheter: choice of catheter depends on the use of the catheter, the condition of the patient, the site of insertion, and how long the catheter is expected to be in place.
 - Various materials
 - Polyurethane or polytetrafluoroethylene catheters are associated with fewer infections compared with polyvinyl chloride and polyethylene.
 - Multiple sizes appropriate for infants and children
 - Different diameters
 - Varying lengths
 - Varying number of ports from one to three
 - Impregnated catheters
 - Antiseptics such as chlorhexidine-silver sulfadiazine
 - Antibiotics such as minocycline-rifampin
 - Heparin
 - Specialized catheters for dialysis and pheresis that are relatively short and have two large-bore ports for optimal blood flow
- Bedside ultrasound (US), sterile protection sleeve, packet of sterile gel if the US is to be used
- Steel hollow needles, guidewire, dilator appropriately sized for patient and catheter; kits containing the catheter, needles, guidewire, vessel dilator, and other equipment necessary for insertion are commercially available.
- Slip-tip syringes
- Heparinized saline flush
- Tubing connectors
- Dressing
 - Sterile, transparent, and semipermeable dressing
 - Sterile gauze dressing if area is bleeding or wet
- Antiseptic disk is optional
 - Chlorhexidine impregnated
 - Silver or calcium alginate impregnated

ANATOMY

The selection of the site for insertion is based on the skill and experience of the operator and the patient's condition and size. The femoral veins are relatively easy to access in nearly all pediatric patients. Although a risk with any site, bleeding is more easily controllable with femoral catheterization. As opposed to adults, the risk of femoral catheterization in infants and children does not appear to present a greater risk of infection than other sites. Use of the internal jugular vein is also relatively safe in most patients. The right internal jugular is associated with fewer complications than the left. Subclavian venous access is noted to have higher complications at the time of insertion, but the catheter is more easily secured and more comfortable for a mobile patient.

Access to the femoral vein in pediatric patients is similar to that in adults. The pulsations of the femoral artery are located below the inguinal ligament, and the vein is accessed medial to the artery about 1 cm below the inguinal ligament. If pulsations are not palpable, the site can be located halfway between the symphysis pubis and the anterior superior iliac spine. The right femoral vein is the preferred site because entry into the inferior vena cava is straighter, with the catheter less likely to enter other minor veins. For right-handed operators, there is more success of entry. Left-handed operators may choose the left femoral vein for easier access. The patient should be supine with legs positioned slightly frog-legged. Often a rolled towel or small blanket is needed underneath the buttocks to elevate and straighten the femoral vessels, allowing easier access.

For internal jugular access, the patient is placed supine in the Trendelenburg position about 30 degrees head down if tolerated. The head is turned away from the side to be catheterized. The right side is preferable because of decreased complications and minimal manipulation to enter the superior vena cava. There are three techniques for entry to the internal jugular veins in children. Become proficient at one rather than attempting all three. The anterior approach is most common. First, identify the carotid artery and the anterior border of the sternocleidomastoid muscle. The insertion site is at the midpoint of this anterior border. The needle should be introduced at a 30-degree angle and aimed at the ipsilateral nipple. The patient is placed in the same position for the subclavian approach, with the head turned away from the site of insertion. The suprasternal notch and the clavicle are identified. The needle is inserted below the lateral two-thirds of the clavicle and aimed at the suprasternal notch.

For subclavian access, a roll is placed between the shoulders and the patient positioned slightly in the Trendelenburg position. The site of entry is just inferior to the lateral and middle junction of the clavicle. The needle is directed to the suprasternal notch and passes underneath the clavicle to enter the subclavian vein.

PROCEDURE

The Seldinger technique is the most common for placing CVCs in infants and children. With ultrasound guidance, this technique is associated with decreased complications and decreased number of attempts in pediatric patients. In extreme circumstances, direct visualization of the vein by cutdown technique may be necessary.

- Seldinger technique
 - Wash hands and put on a sterile gown and gloves.
 - Sterilely prepare the skin with 2% chlorhexidine scrub for at least 30 seconds, with at least 30 seconds of drying time for the chlorhexidine. For the groin, a 2-minute scrub with a 30-second dry time is recommended.
 - Sterilely drape the area using full barrier precautions.
 - If using US guidance, drape the US probe with a sterile US sleeve and secure to the bed.
 - Numb the skin and underlying tissues.
 - Using sterile US gel and the sterilely covered probe, identify the vein.
 - Pass the introducer needle into the vein, aspirating with a slip-tip syringe. The needle can be advanced into the vein after

identifying it with the probe (static guidance) or while the probe is in place (real-time guidance).

- When venous blood enters the syringe easily, disconnect the syringe and pass the guidewire through the needle.
 - The wire must pass easily and without resistance.
 - The patient should be monitored for possible cardiac arrhythmias if the wire enters the heart and causes ectopy.
- Make a small incision at the site of the needle entry as large as the diameter of the vessel dilator.
- Remove the needle, taking care to keep the guide wire in position in the vessel, and then pass the vessel dilator over the guide wire to dilate the vein.
- Remove the vessel dilator, again taking care to leave the guide wire in place.
- Pass the catheter over the wire and into position; then remove the guide wire.
- Aspirate blood and any air from the catheter, and flush with heparinized saline; repeat for all ports.
- Secure the catheter with suture.
- Dress the catheter with the antiseptic-impregnated disk if desired, and then place the transparent dressing.
- Confirm position with a radiograph prior to using the catheter.
 - For subclavian and internal jugular catheters: chest radiograph
 - For femoral catheters: lateral abdominal radiograph to ensure catheter has entered the IVC

AFTER PROCEDURE

Postprocedure Care

Sterile insertion practices as already described and bundled maintenance care have been shown significantly to decrease the risk of CVC-associated bloodstream infections.

- Hand hygiene: prior to manipulating or accessing the CVC, proper hand hygiene should be performed to decrease the risk of pathogen transmission.
 - Wearing clean gloves is also recommended for accessing the CVC to prevent the further transmission of pathogens but to also protect the caregiver from contamination.
- Checklists and CVC kits
 - Providing a checklist of CVC maintenance procedures aids in reminding caregivers of all the steps involved in CVC care.
 - Kits of equipment needed for maintenance procedures, complete with all necessary materials and readily available in one place, aid in ensuring the complete and appropriate performance of routine care.
- The catheter and catheter site must be assessed regularly
 - Daily assessment of the need of the catheter should be reviewed by the healthcare team, including nurses and physicians, and the catheter should be removed if the indications for placement no longer exist.
 - The site should be examined for evidence of infection, such as redness at the site, drainage, swelling, or pain,
 - The catheter should be examined for positioning, especially how much catheter is outside of the skin and whether the securing maneuvers (e.g., suture or device) are still in place.
- The catheter should regularly be assessed (i.e., each nursing shift) for patency. If unable to aspirate and/or flush the catheter, attempts at opening up the lumen with thrombolytics such as TPA should be attempted.
 - The quality of the dressing should be noted: whether it is still occlusive, the presence of wetness under the dressing, and so forth.
- Dressing
 - Catheter site should be cleaned with an antiseptic agent, preferably 2% chlorhexidine-alcohol combination.

- Chlorhexidine has not been labeled for patients younger than 2 months old; however, there are extensive literature and experience showing its safe use in infants as young as immediately following birth.
 - Povidone iodine may be used in patients with a sensitivity to chlorhexidine.
 - The use of iodine ointment is not recommended because of the increased risk of fungal overgrowth.

Types of dressings

- Transparent, semipermeable dressing: allows visualization of the site and does not have to be changed as frequently.
- Gauze and tape: best used when the site is wet from blood, other fluid, or sweat; requires more frequent changes.
- Other dressings such as a silver-impregnated foam dressing may be useful for wet areas or macerated and burned skin.

Dressing change

Frequency

- For transparent, semipermeable dressing: once a week if the site remains clean and dry
- For gauze and tape dressing: no less than every 48 hours
- Dressing should be changed whenever the site is wet.

Procedure

- Caregiver should wear a cap, mask, and sterile gloves.
- Site should be cleaned as it was when the catheter was inserted, most commonly with 2% chlorhexidine-alcohol.
- Antiseptic device replaced if being used
- Catheter resecured with a suture or securement device if needed
- Dressing reapplied and labeled as to when to change again

Infusion tubing: various tubing systems are unit-specific.

- Tubing should be changed regularly but not excessively
 - Administration sets no more than every 72 hours unless soiled
 - Tubing that has administered blood, blood products, or lipids within 24 hours
 - Change caps (if used in the system) no more than every 72 hours and when the administration set is changed.
- Access points must be cleaned with an antiseptic (chlorhexidine or alcohol) by scrubbing and allowing the antiseptic to dry before entering for infusing or aspirating blood.
- Stopcocks are discouraged because of the difficulty in maintaining antisepsis.
- Tubing should be assembled using aseptic or sterile technique.
- Flushing is performed for multiple reasons
 - Check patency of the line.
 - Clear the line of medications or blood products that may cause precipitation if in contact with other medications.
 - Clear the line with heparin-containing fluid to prevent thrombosis.
 - Lock the line or port that is not being used with concentrated heparin or antibiotic/heparin flush.
- Routine replacement of the catheter is not recommended, especially rewiring the catheter, as this is associated with increased risk of infection. Since there is limited venous access, a routine rotation of the CVC in children is not recommended.

Complications

Insertion complications

- Bleeding due to arterial puncture, venous perforation, or coagulopathy
 - External bleeding at the site
 - Hematoma: mostly minor but can be significant, such as neck hematoma from internal jugular placement, causing airway compression or retroperitoneal hematoma from femoral placement

- Hemothorax from internal jugular or subclavian placement
- Hemopericardium rarely occurs.
- Pneumothorax: increased risk with internal jugular and subclavian placement
- Maintenance complications
 - Infection
 - At the site
 - Bloodstream infection is a significant, costly complication that results in morbidity and increases mortality in some patients, but with attention to insertion and maintenance practices can be significantly decreased.
 - Catheter occlusion due to thrombosis or precipitate
 - Vascular thrombosis in vessel; more common with chronic catheters; may be more common than recognized and often results in occlusion and loss of vessel patency, often permanent, and may predispose to infection
 - Catheter erosion can result in pleural effusions or cardiac tamponade.

OUTCOMES AND EVIDENCE

- Measurement of CVP allows the calculation and maintenance of perfusion pressure (mean arterial pressure minus CVP), which provides better tissue perfusion in shock states.
- In a prospective randomized trial comparing pediatric patients with septic shock treated with and without ScvO₂ goal-directed therapy, patients treated with ScvO₂ goal-directed therapy had a significantly lower 28-day mortality (11.8% vs. 39%) and less organ dysfunction than patients without.
- In a prospective study of a planned transition in pediatric ICU patients from the landmark technique for the use of ultrasound guidance, the use of ultrasound to guide placement of CVC was associated with decreased complications and fewer access attempts.
- In a multi-institutional, interrupted time-series design with historical control data in 29 PICUs, utilizing two CVC care practice bundles, an insertion bundle, and a maintenance bundle, the rate of catheter-associated bloodstream infections decreased by 43% from 5.4 to 3.1 infections per 1000 central line days.
- To prevent catheter-associated thrombosis, preventive measures including routine flushing with heparinized saline, the use of heparinized infusion fluids, and the early treatment of a possible occlusion with thrombolytics may decrease rates.
 - A randomized controlled trial comparing a heparinized fluid infusion to nonheparinized in infants with peripherally placed central lines showed a significant decrease in thrombosis requiring catheter removal in the heparinized fluid group (6% vs. 31%).
- The use of US for the percutaneous placement of CVC has been shown in pediatric patients to improve cannulation success and decrease both the number of attempts at cannulation and the time to cannulation.

PULMONARY ARTERY CATHETERIZATION: BEFORE PROCEDURE

Indications

- Pulmonary hypertension, either primary or secondary
- Severe shock unresponsive to fluid resuscitation and vasoactive infusions
- Severe respiratory failure requiring high positive airway pressures with associated hemodynamic compromise

Contraindications

- No absolute contraindications
- Relative contraindications
 - Coagulopathy, which may cause a vascular hemorrhage
 - Tricuspid or pulmonary insufficiency may make bedside placement difficult.
 - Atrial or ventricular arrhythmias may deteriorate owing to the presence of the intracardiac line.
 - Intracardiac shunts, tricuspid insufficiency, or pulmonary insufficiency may make a measurement of cardiac output by the thermodilution method uninterpretable.

Equipment

- For percutaneous placement (not the operative placement of single-lumen catheters), multiple types are available but should be narrow gauge (e.g., 20 gauge) to decrease the risk of intrapulmonary artery thrombosis.
- Sedation and analgesia appropriate for age and condition of the patient
- Skin preparation antiseptic
 - 2% chlorhexidine-based skin prep is recommended.
 - Alternatives include 70% alcohol, tincture of iodine, iodophor.
- Sterile gloves, caps, masks, sterile drapes (large enough for full sterile barrier)
- Swan-Ganz–type pulmonary artery catheter
 - Components
 - Proximal port for CVP
 - Distal port (end hole) for pulmonary arterial and pulmonary occlusion pressure measurement
 - Balloon tip
 - Thermistor at tip of catheter
 - Sizes
 - 5F for patients less than 15 kg
 - 7F for larger patients
 - Variable distance between the ports
 - The proximal port should be in the right atrium (RA).
 - Distal port in the pulmonary artery (PA)
 - Distance between RA and PA in various pediatric patients has been determined and can be used to determine which catheter is appropriate.
- Introducer sheath: one French size larger than the catheter, with a sterile sleeve to cover the catheter
- Heparinized saline flush

- Pressure tubing with a transducer connected to a monitor so pressure tracings can be monitored during catheter placement

■ ANATOMY

The site of placement depends on many factors, including the skill of the operator, size of the patient, presence of coagulopathy, medical condition of the patient, and accessibility of the vein. The sites most commonly used are the femoral veins, internal jugular veins, and subclavian veins. Although any of these sites will allow passage of the catheter into the right atrium and on into the right ventricle and pulmonary artery, less manipulation of the catheter is needed using the right internal jugular vein or the left subclavian vein. However, the right femoral vein also requires less manipulation and is very commonly used because of its easier accessibility and fewer complications in patients with bleeding diatheses, and there is essentially no risk of pneumothorax in patients with severe lung disease. Other veins at these locations can also be used, but more manipulation may be necessary for bedside placement.

■ PROCEDURE

- Single-lumen pulmonary arterial catheter is placed with direct visualization in the operating room.
- The Swan-Ganz–type PA catheter is placed percutaneously.
 - Using sterile technique and full barrier precautions, as in the placement of a central venous catheter, the introducer sheath is placed using the Seldinger technique.
 - The catheter is passed through the introducer sheath and the sterile sleeve. During insertion, the balloon is inflated to allow the catheter to follow the blood flow, and the distal port is transduced so the pressure tracing can be monitored. The tracing is noted to be that of a right atrial trace initially. Then, as the catheter passes the tricuspid valve, the tracing becomes that of a ventricular pressure trace with a low diastolic pressure. The catheter is then allowed to flow into the pulmonary artery, and the tracing is that of an arterial trace, with the systolic pressure being the same as the right ventricle, but the diastolic pressure being higher. The catheter, still with the balloon inflated, is then advanced into the pulmonary arterial occlusion position, and again the trace is that of an atrial trace but with slightly higher values than the right atrial trace. The balloon is then deflated, and the pulmonary arterial trace should recur. If not, the catheter should be pulled back until a good pulmonary artery trace is seen, and then the balloon is reinflated to confirm the catheter will “wedge” or float into the occlusion position. As the catheter is advanced, attention must be paid to the ECG, as atrial or ventricular ectopy may occur. The major difference in passing the catheter in pediatric patients is that the turns and torques of the catheter must be made with more finesse than in adults because the distances are shorter, and the cavities of the right atrium and ventricle are smaller.
- Bedside ultrasound may be useful when passing the catheter to confirm the location.
 - After the catheter is stable in a good position, it should be secured within the sterile sleeve. The introducer sheath should be secured with a suture and the site dressed as with a central line.
 - A chest radiograph should be performed to confirm proper positioning.
- Measurement of thermodilution cardiac output
 - A known volume of fluid at a lower temperature than blood (either iced or room temperature) is injected into the proximal port of the catheter, and the temperature change at the thermistor is noted. The amount of heat loss allows for the calculation of flow.
 - A smaller volume of injectate is used in the 5F catheter to avoid fluid overload of the patient.

- Iced injectate is not recommended in pediatrics because repeated measures may result in hypothermia for small infants and children.
- Room temperature injectate is recommended for smaller pediatric patients.
- The type of fluid injected also must be taken into consideration for the pediatric patient if repeated measures are to be made (usually should be normal saline).
- Generally, three injections should be made during each measurement period, and with repeated measurements, that volume can potentially affect the electrolytes of the pediatric patient.
- The cardiac output measured in this way is reported and divided by the patient's body surface area as the cardiac index.

■ AFTER PROCEDURE

Postprocedure Care

- Catheter care and dressing as for the central venous line
- Balloon is never left inflated because of the risk of pulmonary infarction
- Continuous monitoring of both the right atrial (proximal) port and the pulmonary arterial port (distal) to ensure that the catheter stays in the proper location
- Regular chest radiographs to confirm the catheter position

Complications

- At the time of accessing the vein
 - Bleeding
 - Pneumothorax when the internal jugular or subclavian veins are used
- During catheter placement and positioning
 - Arrhythmias are most common.
- Prolonged use
 - Infection at the site or in the bloodstream
 - Rarely, endocarditis
 - Trauma to the tricuspid or pulmonary valve is usually clinically insignificant but may predispose the patient to endocarditis
 - Arrhythmias
 - Thrombosis of the vein of entry or the pulmonary artery
- Rare
 - Pulmonary infarction
 - Rupture of the pulmonary artery with balloon inflation

■ OUTCOMES AND EVIDENCE

- Monitoring PA pressure in the postoperative period in infants undergoing cardiac surgery has been shown to help guide therapy in prospective descriptive studies but not randomized controlled studies.
- Using cardiac output as measured by thermodilution has been helpful when guiding resuscitation during shock in pediatrics.
- Studies showing an improved outcome using the PA catheter are not available.

INTRAARTERIAL CATHETER: BEFORE PROCEDURE

Indications

- Continuous measurement of the arterial blood pressure
 - Hemodynamic instability with real or potential hypotension
 - Severe hypertension requiring continuous vasoactive infusions
 - Measurement of cerebral perfusion pressure in patients with increased ICP
- Frequent assessment of arterial blood gases
- Rarely, frequent blood sampling in patients who have relative contraindications to central venous access (e.g., diabetic ketoacidosis)

Contraindications

- Perfusion of the extremity distal to the arterial catheterization would be compromised by the catheter placement.
- Skin disruption at the site of insertion
- Coagulopathy is a relative contraindication.

Equipment

- Seldinger technique
 - Butterfly catheter and small-gauge wire: 0.15 or 0.18 cm
 - Steel needle or butterfly catheter, small-gauge wire (0.15 or 0.18 cm), and small peripheral vascular catheter or 2.5F single-lumen catheter
 - Peripheral vascular catheter size can vary from a 24 gauge in small infants to 20 gauge in adolescents; larger catheters are not indicated.
- Sterile site preparation
 - Skin preparation pads, either 3% chlorhexidine or alcohol
 - Sterile gloves
 - Sterile towels
 - Sterile drapes
- Analgesic agents
 - 1% lidocaine local with a 25-gauge needle and syringe
 - Topical anesthetic such as EMLA
- Heparinized saline flush solution
- Tubing set
 - Luer-Lok tubing to attach to the catheter: type depends on PICU nursing standards
 - Pressure tubing to extend to the pressure transducer
 - Pressure transducer connected to monitor
- Securement equipment: tape, suture, and/or clear adherent dressing

ANATOMY

Arterial catheterization is performed in pediatric patients using the peripheral and femoral arteries. For neonates, the umbilical artery is used. The peripheral arteries most commonly used in pediatrics are the radial, dorsalis pedis, and posterior tibial arteries. Ulnar arteries can also be used, but attention should be paid to the patency of the radial artery prior to accessing the ulnar artery. The femoral artery is also accessible in pediatric patients.

PROCEDURE

- Apply topical analgesic in patients who are conscious or minimally sedated.
- Prepare the skin and drape for the sterile procedure.
- Inject 1% lidocaine local in the skin and around the artery, taking care to aspirate to avoid intraarterial injection.
 - Ultrasound may be used to locate the artery and facilitate successful catheter insertion using a static or real-time technique.

- For direct insertion
 - Direct catheter toward artery, and when arterial blood flows back into the catheter, carefully advance catheter about 1 to 2 mm, and then remove stylet.
 - Attach the connecting tubing and aspirate blood, removing air bubbles, and then inject heparinized saline. Blood should be easily aspirated into the syringe.
- Using the Seldinger technique (the most common technique for femoral arterial access but can be used for any commonly used artery)
 - Using a steel or butterfly needle with the tubing detached, direct the needle toward the artery.
 - When arterial blood is obtained and flowing freely, advance the guide wire through the needle; it should pass easily with no resistance.
 - Then remove the needle and pass the catheter over the wire and into the artery.
 - Remove the wire and attach the connecting tubing; aspirate blood, removing air bubbles, and then flush with heparinized saline. The blood should be easily aspirated into the syringe.
 - Attach the connecting tubing to the high-pressure tubing and transducer, allowing the arterial waveform to be visualized.

AFTER PROCEDURE

Postprocedure Care

- Continuous blood pressure monitoring with appropriate alarms
- Continuous fluid delivery, most commonly with heparin-containing fluid to prevent clot formation in the catheter
- Frequent evaluation of the system to detect any disruption of the catheter system
- Frequent evaluation of perfusion to the extremity distal to the catheter and the skin in the area around the catheter
- Evaluation of the securement of the catheter to prevent inadvertent dislodgment
- Dressing changes, including cleaning of the site to prevent infection

Complications

- Bleeding at the site
 - At the time of insertion, this can be minor.
 - If the patient is coagulopathic, bleeding may be more of a concern.
- Ischemia distal to the catheter
 - Due to compromise of arterial flow
 - Embolic
 - Thrombotic
 - Injuries may be severe, including the loss of toes, fingers, feet, hands, or even legs.
- Infection is rare with percutaneous catheters.
- Exsanguination
 - May occur if any part of the arterial catheter system becomes disconnected
 - Prevented by continuous monitoring with appropriate alarms that can immediately detect a loss of blood pressure
 - Frequent observation and checking of the system are also necessary.

OUTCOMES AND EVIDENCE

- No randomized controlled studies on the use of arterial monitoring and outcome are available in pediatrics.
- In a data analysis of a pediatric prospective data registry with more than 10,000 patients with arterial lines, 10.3% exhibited complications associated with arterial catheters.
 - Complications are more common in younger patients, patients with catheters placed later in the hospital course, and certain procedures

- Cardiac surgery, dialysis, and bone marrow transplantation
 - Most common associated complications were catheter-related infections, mechanical complications, and arterial thromboembolism.
 - Serious complications such as amputation were rare (0.6%).

DEFIBRILLATION: BEFORE PROCEDURE

Indications

- Documented or suspected ventricular fibrillation (VF) or pulseless ventricular tachycardia
 - VF in pediatrics is associated with multiple clinical scenarios.
 - Dilated cardiomyopathy
 - Myocarditis
 - Drug intoxication
 - Underlying congenital heart disease
 - Prolonged QT syndrome
 - Sudden blow to the chest (e.g., a baseball)
 - Electric shock
 - Severe electrolyte abnormalities (e.g., hyperkalemia)

Contraindications

- No contraindications in a patient with proven or suspected VF

Equipment

- Defibrillator
 - Monophasic type: older
 - Biphasic type: requires lower energy
 - Automatic external defibrillators (AEDs)

ANATOMY

The placement of the pads or paddles is essentially the same as for adults. One is placed on the upper right side of the chest and the other at the apex of the heart, directly over the heart and to the left of the left midclavicular line. For some infants, because their chest is so small, the pads/paddles may still touch in this location. In this case, the pads/paddles may be placed in an anterior/posterior position with one placed on the chest to the left of the sternum and another on the back below the scapula.

PROCEDURE

- Follow Pediatric Advanced Life Support (PALS) defibrillation sequence recommendations.
- Place pads or paddles in the proper location.
- Manual defibrillation: useful in all ages and sizes of pediatric patients
 - Select energy
 - 2 J/kg for the first shock
 - 4 J/kg for subsequent attempts
- Automatic external defibrillation
 - Different brands of AEDs have varying ability to defibrillate pediatric patients. It is best to use a device with pediatric attenuation ability and one that can recognize pediatric shockable rhythms (PALS).

- Apply patches and follow instructions given by AED if a shockable rhythm is present.

AFTER PROCEDURE

Postprocedure Care

- Determine the treatable causes of VF and treat.
- Start antiarrhythmic agents to prevent recurrence.

Complications

- Major complication is inability to convert to perfusing rhythm or deterioration into asystole; may be converted into another arrhythmia
- Skin burns are the most common complication and rarely are clinically significant.
- Myocardial damage can occur, but using doses of more than 4 J/kg have been reported to have few adverse effects.
- Blood clots have been reported in adults.

OUTCOMES AND EVIDENCE

- Defibrillation using a dose of 2 J/kg was successful in 91% of shocks in a retrospective study of children.
- Out-of-hospital pediatric patients with ventricular fibrillation had a 20% chance of surviving to discharge from a secondary analysis of data from a randomized controlled study of out-of-hospital airway management.
- In hospitalized pediatric patients with cardiac arrest whose initial rhythm was ventricular fibrillation or ventricular tachycardia, a survival-to-discharge rate of 35% was reported in a National Registry of Cardiopulmonary Resuscitation prospective data analysis.
- AEDs have been shown to be effective for pediatric patients older than 1 year of age in multiple studies; use of AEDs in high-risk patients younger than 1 year has been shown to be effective.

CARDIOVERSION: BEFORE PROCEDURE

Indications

- Hemodynamically unstable atrial tachycardias
 - Supraventricular reentry tachycardia
 - Atrial flutter
 - Atrial fibrillation
- Atrial tachycardias that have failed medical management

Contraindications

- Ectopic tachycardias will not be converted
 - Atrial ectopic tachycardia
 - Junctional ectopic tachycardia
- Unstable ventricular tachycardia or VF, which need to be defibrillated
- Patients on digoxin will have a lowered VF threshold and may develop VF with cardioversion.
- Patients with chronic atrial fibrillation or atrial flutter are at risk of embolism from atrial thrombi and should not be cardioverted until a transesophageal echocardiogram shows no evidence of thrombus.

Equipment

- Defibrillator with the ability to synchronize the discharge with ECG
- Sedation and analgesia should be provided following safe sedation guidelines.

ANATOMY

The placement of the pads or paddles is essentially the same as for defibrillation. One is placed on the upper right side of the chest and the other at the apex of the heart, directly over the heart and to the left of the left midclavicular line. For some infants, because their chest is so small, the pads/paddles may still touch in this location. In this case, the pads/paddles may be placed in an anterior/posterior position with one pad on the chest to the left of the sternum and one pad on the back beneath the left scapula.

PROCEDURE

- Apply appropriately sized pads or paddles to the chest.
- Attach the ECG pads for the defibrillator or position the paddles such that a good ECG trace is obtained.
- Turn the defibrillator setting to synchronous mode.
- Set the energy to 0.5 to 1 J/kg.
- Hold the discharge button down until the dose of energy is delivered, which will occur after the defibrillator has detected two to three complexes.

AFTER PROCEDURE

Postprocedure Care

- Observe the rhythm for recurrence.
- Begin antiarrhythmic therapy based on the original rhythm and the presence of an underlying heart disease.
- Observe the skin for evidence of burns.

Complications

- Other abnormal rhythms can occur
 - If VF occurs, change the mode to asynchronous, and immediately defibrillate with 2 J/kg and follow the PALS VF sequence.
 - Bradycardias may occur and are usually transient, but if persistent may administer atropine.
- Thromboembolism may occur if atrial thrombi are present and may result in stroke or limb ischemia.
- Skin burns may occur but are rare with the low dose of energy.
- Myocardial injury is possible but rare at this low dose of energy.

OUTCOMES AND EVIDENCE

- Cardioversion was known to be effective in atrial arrhythmias more than 80% of the time in a prospective observational study.

- Blinded randomized trials of cardioversion versus other methods of converting atrial arrhythmias have not been done in children.

TEMPORARY CARDIAC PACING: BEFORE PROCEDURE

Indications

- Symptomatic bradycardia
 - Sinus bradycardia not usually symptomatic or improves with adequate oxygenation and ventilation
 - Other bradydysrhythmias will often respond to atropine or β -adrenergic agonists
- Symptomatic advanced-grade heart block may require temporary or permanent pacing
 - Congenital complete atrioventricular block
 - Postoperative heart block
- Ingestion of medications often require only temporary pacing until the drug effect resolves.
 - Beta-blockers
 - Digoxin
 - Calcium channel blockers
- Pace termination of tachydysrhythmias such as intraatrial reentrant tachycardia (IART)

Contraindications

- Absolute contraindications
 - Temporary transvenous ventricular pacing
 - Presence of a prosthetic tricuspid valve
 - Epicardial pacing
 - No absolute contraindications
 - Transesophageal pacing
 - AV block, because the ventricle cannot be reliably paced from the esophagus
 - Esophageal abnormalities such as tracheoesophageal fistula or recent esophageal surgery
 - Transcutaneous pacing
 - Severe chest trauma that prohibits the application of patches
 - Transthoracic pacing
 - Indicated only in extreme circumstances, no absolute contraindications
- Relative contraindications
 - Temporary transvenous ventricular pacing
 - Severe hypothermia, secondary to risk of fibrillation during rewarming
 - Digitalis toxicity, secondary to the risk of ventricular dysrhythmias
 - Coagulopathy
 - Epicardial pacing
 - Dense fibrous scar around the heart may make placement difficult or lead to high thresholds.
 - Transesophageal pacing
 - Postorthotopic heart transplant, because the tissue near the esophagus is recipient left atrial tissue and electrically isolated from the donor's heart.

- Transcutaneous pacing
 - Capture may be impossible in extreme obesity, pericardial effusion, or increased thoracic capacity.
- Transthoracic pacing
 - Indicated only in extreme circumstances
 - Pacing during cardiac arrest is typically futile.

Equipment

- Bipolar transvenous pacing catheters, active fixation (must be placed under fluoroscopy) or balloon-tipped, commercially available in size 3F and larger
- Temporary pacing box (ensure adequate battery supply) with connection cables
- Long introducer needle or commercially available kit as needed if a transthoracic puncture intended
- External pacing pads and unit; suggest a defibrillation unit and paddles or pads, also available
- Temporary pacing wires per surgeon preference at the time of sternotomy

PROCEDURE

First, establish a stable airway and adequate ventilation and oxygenation, and consider atropine or β -adrenergic agonists.

Temporary Transvenous Ventricular Pacing

- Choice of vein dependent on operator comfort and skill (frequently right internal jugular; may also use femoral). It may require fluoroscopy to manipulate into right ventricle or subclavian veins. Consider avoiding the left subclavian vein if the patient is a candidate for a permanent transvenous system, usually greater than 20 kg.
- Bedside placement typically requires a balloon-tipped catheter; consider placement under fluoroscopic guidance if time permits.
- Under sterile conditions, the introducer sheath is placed in the central vein by a modified Seldinger technique; consider the use of ultrasound guidance.
- If the vein diameter permits the placement of a sheath one French size larger than necessary for the pacing catheter, then the side-arm of the sheath may be used for central venous access as well.
- Catheter is advanced under sterile procedure from the central vein through the sheath to right atrium and across the tricuspid valve into the right ventricle. The position is confirmed by attaching the catheter leads either to the ECG and noting intracardiac electrograms (sharp spikes that correspond to surface P waves when the catheter tip is in the atrium or to surface QRS when the catheter tip is in the ventricle) or by attaching the catheter leads to a pacing box and noting atrial or ventricular capture.
- Threshold testing is performed as follows: pacemaker output is decreased incrementally until a loss of capture is noted, then the output is increased to double the pacing threshold to ensure an adequate safety margin.
- A temporary pacing lead is secured in place, typically with sutures and/or clear adhesive dressing, and the position is confirmed by chest x-ray or echocardiogram.
- Pacing mode depends on the clinical circumstance. Ideally, this would be a demand mode such as VVI or DDD to inhibit pacemaker output when the intrinsic beat is sensed, thus preventing pace induction of tachydysrhythmias or ventricular fibrillation. However, when the sensing thresholds are marginal, asynchronous pacing may be necessary.
- Pacing and sensing thresholds should be determined at least daily while the patient requires a temporary pacemaker.

Epicardial Pacing

- Temporary pacing wires may be placed by the cardiothoracic surgeon at the time of sternotomy, typically one bipolar lead on the

atrium (commonly placed to the right of the sternum) and one bipolar lead on the ventricle (commonly placed to the left of the sternum). Wires are then tunneled through the anterior chest wall and secured in place.

- Pacing wires may be connected to a temporary pacing box if clinically needed.
- Threshold testing and the selection of a pacing mode is performed as detailed earlier.
- Removal of temporary pacing wires occurs with gentle traction.

Transesophageal Pacing

- Relatively easy technique for pacing atrium, especially “overdrive” pacing of atrial tachydysrhythmias; not useful for pacing the ventricle and typically uncomfortable
- A standard transvenous pacing catheter is lubricated and advanced through the nose into the distal esophagus to the approximate level of the atrium.
- As the catheter is passed, it may be helpful to connect leads to the ECG. The location where the ECG signal voltage is the greatest should be the position where pacing will be the most effective.
- Catheter is connected to the pacing box.

Transcutaneous Pacing

- Very painful, best reserved for unconscious or heavily sedated patients
- Two sizes of pacing patches available: pediatric size for patients up to 15 kg, adult size recommended for patients over 15 kg
- Patches are placed on the patient's chest, labeled front (negative electrode) and back (positive electrode); may also be placed on the right chest and apex of the left ventricle
- Since the current must traverse the chest wall, the output required is typically large, up to 200 milliamps, with a wider pulse width of 20 to 40 msec. Once ventricular capture is achieved, the output is decreased as much as possible.

Transthoracic Ventricular Pacing

- Rarely indicated in desperate situations, when other access to ventricular pacing has failed
- Requires long introducer needle or a commercially available kit
- Skin is prepped and draped under sterile precautions.
- Introducer needle attached to a slip-tip syringe is advanced from the left xiphocostal angle 30 degrees to skin, directed toward the left shoulder while aspirating. Aspiration of blood confirms needle placement in the right ventricle.
- Pacing catheter or wire is advanced into the right ventricle and secured in place; the position is confirmed by x-ray or echocardiogram.

AFTER PROCEDURE

Postprocedure Care

- Continuous monitoring of cardiac rhythm through telemetry
- Sedation and/or analgesia as warranted
- Conversion of the pacing mode as feasible to temporary transvenous or permanently implanted device if clinically indicated
- Routine reevaluation of pacing and sensing thresholds at least daily, and the reassessment of underlying cardiac rhythm and the need for continued pacing

Complications

- Temporary transvenous ventricular pacing
 - Complications of venous access (failure to gain access, bleeding, pneumothorax, and infection)

- Complications of pacing leads (dysrhythmias, cardiac perforation, and a loss of capture)
- Epicardial pacing
 - Rarely, bleeding or infection
- Transesophageal pacing
 - Chest pain is common and typically requires analgesia or sedation.
 - Esophageal perforation (rare)
- Transcutaneous pacing
 - Pain
 - Failure to capture
- Transthoracic pacing
 - Cardiac tamponade is common.
 - Injury to the heart or great vessels, pneumothorax or hemothorax, coronary artery laceration, liver, or lung laceration

OUTCOMES AND EVIDENCE

- Patient outcomes after temporary cardiac pacing primarily related to the underlying condition
 - Outcome following cardiac surgery in most centers is excellent. The majority of patients requiring postoperative pacing will not require a permanent implanted pacemaker.
 - Outcome of temporary pacing performed during cardiopulmonary resuscitation is poor.
- There is current debate regarding the prophylactic placement of temporary pacing wires in all pediatric patients undergoing heart surgery. Perhaps lower risk patients do not need empiric pacing wires placed in the operating room (OR).
- Temporary pacing wires placed in the OR may be used in up to 30% of postoperative congenital heart patients, with half of those uses for diagnostic rather than pacing purposes. The need to use temporary wires is higher if the patient has decreased cardiac function, a need for multiple catheters, or required cardioversion in the operating room.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY: BEFORE PROCEDURE

Since the transthoracic echocardiographic windows of pediatric patients are often superior to those of adults, the development of transesophageal echocardiography (TEE) in children initially lagged behind its development in adults. Presently, however, TEE has assumed a critical role in the evaluation of children with congenital and acquired heart disease.

Indications

- Need for echocardiographic evaluation in patients with inadequate or nondiagnostic transthoracic windows
 - Patients with intraatrial baffles
 - Suspected thrombus or vegetation on intravascular devices or heart valves
 - Aortic dissection
 - Recent postoperative patient with poor transthoracic windows
- Perioperatively at the time of cardiac surgery
 - Preoperatively
 - Specifically characterize congenital heart disease prior to planned surgical intervention
 - Postoperatively
 - Evaluate for intracardiac air prior to weaning from cardiopulmonary bypass.
 - Evaluate for residual defects such as shunts, valvular insufficiency, residual obstruction, and myocardial dysfunction.
 - 2% to 15% of planned cardiac surgical procedures significantly changed based on the results of the intraoperative TEE.
- Cardiac catheterization laboratory
 - During interventions, such as atrial and ventricular septal defect occluder devices, balloon valvuloplasty procedures, stenting procedures, and endomyocardial biopsies

Contraindications

- Relative contraindications
 - Unrepaired tracheoesophageal fistula
 - Recent esophageal surgery
 - Esophageal obstructive lesions
 - Active gastrointestinal bleeding
 - Perforated viscus
- Other considerations
 - Since neck flexion and extension are frequently required for probe placement, cervical spine abnormalities should be ruled out prior to the procedure.
 - For patients who require anticoagulation, parameters should be maintained at the lower end of the therapeutic range.

Equipment

- Appropriately sized TEE probe
- Echocardiogram (ultrasound) machine

PROCEDURE

Since the size of the probe relative to the size of the esophagus and adjacent structures is larger in pediatric patients, and because patients must be cooperative for the procedure to be performed safely. TEE in pediatric patients is performed under deep sedation or, more commonly, general anesthesia. Endotracheal intubation for airway protection and controlled ventilation is recommended for smaller patients at an increased risk of mechanical airway compromise—for example, children with systemic illnesses that increase their risk of respiratory depression with sedation, children at an increased risk of aspiration or impaired airway control, and children with poor underlying cardiopulmonary status such as severe cyanosis or poor ventricular function. The TEE probe is lubricated and advanced through the oropharynx into the esophagus. The passage of the probe into the esophagus may be facilitated by flexion of the patient's neck or a jaw lift maneuver. A complete two-dimensional color Doppler and pulsed-wave and continuous-wave Doppler interrogation of the cardiac chambers, valves, and great vessels is then performed as clinically indicated.

The greatest strength of TEE lies in its ability to image the heart and great vessels not adequately accessible through transthoracic windows, especially the more posterior cardiac structures. These include the delineation of atrial anatomy, pulmonary veins, and systemic venous

return, both in patients with unrepaired congenital heart disease and in patients post intraatrial baffle procedures. TEE may also be useful in examining the atrioventricular valves, the left ventricular outflow tract, levels of pulmonary outflow tract obstruction, the pulmonary artery confluence, and proximal branch pulmonary arteries. Limitations to TEE include imaging structures obstructed by bronchial air and limited imaging planes available from the esophageal window.

As technology has progressed, miniaturization of echocardiographic probes has permitted transesophageal imaging with increasingly greater resolution even in smaller patients. A commercially available 8F (2.5-mm diameter) probe designed for intracardiac echocardiography (ICE) may be used off-label for monoplane transesophageal imaging, even in neonates less than 2 kg. Also recently available are the first real-time three-dimensional TEE probes, which permit the accurate evaluation of three-dimensional cardiac structures and may prove valuable in TEE-guided catheter-based interventions.

AFTER PROCEDURE

Postprocedure Care

- After removal, the TEE probe should be examined for evidence of blood, suggesting pharyngeal or esophageal injury.
- Post-TEE airway management as clinically indicated

Complications

- Common
 - Mild mucosal injury
- Infrequent
 - Inability to successfully intubate the esophagus
 - Airway compromise likely related to compression of the membranous trachea
 - Compression of posterior vascular structures such as the descending aorta or pulmonary veins
- Serious, rare complications
 - Significant injury to the pharynx, esophagus, or stomach

OUTCOMES AND EVIDENCE

- Outcomes in pediatric TEE depend largely on the surgical or catheter-based interventions performed at the time of the echocardiographic exam.
- Intraoperative TEE has been shown to impact decision making in approximately 2% to 15% of cardiopulmonary bypass cases.

FLEXIBLE BRONCHOSCOPY: BEFORE PROCEDURE

Indications

Under most circumstances, flexible airway endoscopy in critically ill children should be undertaken by an experienced pediatric bronchoscopist.

- Airway evaluation
 - Smoke inhalation
 - Airway trauma
 - Stridor (acute, postextubation)
 - Suspected airway lesion
 - Wheezing unresponsive to medical therapy
 - Localized hyperinflation
 - Suspected congenital anomalies
 - Hemoptysis*
 - Detection of suspected foreign body*
 - Postoperative evaluation of anastomotic sites
- Airway management
 - Difficult intubation
 - Facilitate extubation
 - Evaluation of the position of the ETT
- Collection of samples for diagnostic purposes
 - Persistent pulmonary infiltrate
 - Aspiration
 - Immunocompromised host with pulmonary infiltrate
 - Endobronchial and transbronchial biopsy of a mass
- Therapeutic indications
 - Selective bronchial intubation
 - Removal of large mucous plugs and respiratory secretions
 - Removal of bronchial casts
 - Instillation of surfactant in acute lung injury
 - Instillation of mucolytic agents in refractory atelectasis
 - Fibrin glue therapy for the treatment of bronchopleural fistula

Contraindications

- Absolute contraindications
 - Airway size too small for the available bronchoscope
 - Massive hemoptysis
 - Severe cardiovascular instability
 - Lack of trained personnel, inadequate equipment
 - The procedure will elicit no information of value.
- Relative contraindications
 - Bleeding diathesis
 - Severe pulmonary arterial hypertension
 - Profound hypoxemia despite 100% oxygen supplementation
 - Significant risk of cerebral herniation
 - Unstable arrhythmia
 - PEEP greater than 10 cm H₂O
 - Active bronchospasm
 - Mean arterial pressure less than 65 mm Hg on vasopressor therapy

Equipment

- A number of directable, flexible bronchoscopes are available for pediatric use, and each instrument has unique characteristics and limitations
 - The 2.2-mm ultrathin bronchoscope does not have a suction channel, but it may pass through ETTs with internal diameters as small as 2.5 mm, and therefore, it is extremely useful in the neonatal ICU.
 - In nonintubated infants and children intubated with 3.5- to 4.5-mm ETTs, the 2.7- to 2.8-mm bronchoscopes are especially useful and less prone to obstruct the airway than larger instruments.
 - A 3.4- to 3.8-mm bronchoscope is the most commonly used endoscope that can be used in nonintubated children aged 2 to 10 years or in children intubated with 5.0- to 6.0-mm ETTs.

*Rigid rather than flexible airway endoscopy by an experienced pediatric otolaryngologist or airway surgeon should be considered in critically ill children with massive hemoptysis or a suspected foreign body.

- The instrument most commonly used in adults and larger children is 4.7 to 4.9 mm in outside diameter and has a 2-mm suction channel.
- Topical lidocaine solution 2% for the nose and larynx, 1% for the lower airway (maximum dose should not exceed 5-7 mg/kg)
- Oxygen source and tubing
- Bag and mask, laryngoscope, and ETTs
- 1:10,000 epinephrine for management of airway bleeding (0.1 mL epinephrine in 5-10 mL NS)
- Two wall-mounted suction units (one for the bronchoscope)
- Resuscitation drugs and equipment
- Clear airway endoscopy mask in nonintubated children allows simultaneous insertion of the bronchoscope through a side port and delivery of continuous positive airway pressure.
- An adapter attached to the ventilator circuit and ETT, with an aperture that seals around the bronchoscope
- Specimen traps and syringes
- Sterile normal saline to be used for instillation
- Lidocaine jelly to anesthetize the nasal passage in nonintubated patients
- Water-soluble lubricant for the bronchoscope
- Video camera, recorder, and high-resolution television monitor placed on a mobile cart

ANATOMY

In addition to obvious size differences between pediatric and adult airways, there are anatomic differences that predispose the infant and young child to an airway obstruction with respiratory illness or manipulation. Thus, in nonintubated children, specific techniques that take into account these anatomic differences may be required to maintain airway patency and prevent airway injury.

- The tongue: relatively larger in proportion to the oral cavity
- The posterior pharynx: on the posterior wall, and often extended into the choana, adenoid tissue can be seen in young children.
- The larynx: the infant larynx lies nearly two vertebral bodies higher in the neck than that of the adult and is located more anteriorly; laryngeal structures are more compliant.
- The epiglottis has a much more pronounced curvature (omega-shaped) that is angled away from the tracheal axis.
- The arytenoid cartilages may be very prominent in the infant.
- The first tracheal ring (i.e., the cricoid cartilage) is the smallest cross-sectional area of the airway in young children.
- The normal shape of the trachea in children is nearly round, with cartilages extending visibly through an arch approximately 320 degrees. The membranous portion of the trachea is more mobile in the upper third of the trachea.
- The carina is very sharp in adults, but it is often blunted in children. The right main stem bronchus is immediately seen upon peering down the trachea.
- The right lung
 - The right upper lobe takes off just beyond the carina, and the lobar bronchus is very short and has three segmental bronchi including the anterior, posterior, and apical.
 - The right middle lobe takes off at an acute angle anteriorly and divides into lateral and medial segments.
 - The basilar segments of the lower lobe may be variable and include apical, medial, anterior, lateral, and posterior segments.
- The left lung
 - The left upper lobe divides into the apical posterior and anterior segments and lingular segments.
 - The lower lobe bronchi are variable and include apical, antero-medial, lateral, and posterior segments
 - In pediatric practice, as opposed to adult practice, it is rarely useful specifically to identify bronchi smaller than the segmental branches.

Procedure-Related Considerations

- Communication between the critical care team and bronchoscopist is essential to establish whether flexible airway endoscopy is the most appropriate approach for the evaluation and/or management of the patient's airway or pulmonary problem, what procedure should be performed, and what additional preprocedural evaluation of the patient is required.
- In general, the bronchoscopist should evaluate the patient's cardiopulmonary stability; review metabolic, hematologic, and coagulation laboratory results; review chest radiographs; and determine the size, if present, of any artificial airways.
- Patients who are known to be at risk for bronchospasm should be given preprocedure bronchodilators and steroids.
- Even intubated patients may aspirate around a cuffed ETT when the tube is moved during manipulation of the bronchoscope; therefore, the stomach should be emptied prior to the procedure (fasting 4-6 hours for milk and solids and 3 hours for water).
- In the child with a brain injury, flexible airway endoscopy should be performed with caution because the ICP may transiently but significantly increase during the procedure.

PROCEDURE

- Sedation and monitoring
 - In children undergoing flexible airway endoscopy, sedation is almost always required to obtain useful information and avoid discomfort and airway trauma.
 - Appropriate monitoring of critically ill children undergoing flexible airway endoscopy includes the presence of a second physician (intensivist preferred).
 - Continuous monitoring of oxygen saturation, respiratory rate, and cardiac rate and rhythm, as well as intermittent (or continuous) monitoring of blood pressure
- Oxygenation and ventilation
 - Although the bronchoscope may occupy 10% of the tracheal lumen in a nonintubated patient, the instrument takes up a larger percentage of available space in an ETT.
 - The presence of a bronchoscope in the airways results in physiologic alteration including increased airway resistance associated with decreased minute ventilation. In spontaneously breathing patients, expiratory resistance will increase more than inspiratory resistance; in intubated patients, gas exchange may be dramatically altered.
 - Positive end-expiratory pressure (PEEP) should be reduced to avoid large, inadvertent increases in PEEP due to increased expiratory resistance.
 - Patients undergoing bronchoscopy are always at risk for hypoxia. Therefore, supplemental oxygen should be given, and Sao_2 should be maintained above 90% throughout the procedure.
 - Suctioning should be limited to the shortest possible time because it removes gas from the lungs and may cause hypoxemia.
- Diagnostic/therapeutic techniques
 - Bronchoalveolar lavage (BAL)
 - Contamination from the upper airway occurs, because the bronchoscope traverses either the upper airway or ETT.
 - The procedure for BAL in children is not standardized.
 - The number and size of non-bacteriostatic saline aliquots instilled remains controversial, but typically 2 to 5 aliquots of 0.5 to 1 mL/kg, usually not exceeding 20 mL/aliquot, are utilized.
 - The usual return of BAL fluid is 40% to 60%. In most clinical laboratories, a minimum of 5 to 10 mL of BAL fluid is usually required to perform total cell and differential counts, as well as standard pathologic and microbiologic studies.
 - The importance of total and differential cell counts and a pathologic evaluation of BAL fluid should not be

underestimated. Consultation with an infectious disease specialist, pathologist, and/or the microbiology laboratory may be helpful in prioritizing studies and improving the diagnostic yield of BAL fluid studies.

- The position of the ETT should be checked at the end of the procedure.
- Protected specimen brush (PSB)
 - Brush is protected from upper airway contamination by an outer catheter and occluding plug.
 - While passed through the instrument channel of the bronchoscope, the sheathed brush does not come into contact with the upper airway or ETT secretions.
 - Once the catheter is in the distal airway, the plug is removed and the sample is collected.
- Bronchoscopic needle aspiration (BNA)
 - Used for sampling of lymph nodes located in the paratracheal, subcarinal, and perihilar areas
 - Can be used in the diagnosis of endobronchial lesions
 - Used mostly in adults for the diagnosis and staging of thoracic malignancies
- Endobronchial ultrasound (EBUS)
 - Enables the visualization of extra-airway structures that cannot be seen through the bronchoscope
- Laser bronchoscopy
 - In patients with an airway obstruction due to surgically unresectable malignancies
 - Preparation of airways for insertion of airway stents
 - Exclusively used in adults

AFTER PROCEDURE

Postprocedure Care

- Careful monitoring should be continued after the procedure, at least until the child has returned to pre-flexible airway endoscopy neurologic and cardiopulmonary status.
- The ability to rapidly reintubate the patient is essential.
- Chest x-ray indicated in patients whose respiratory status does not return to preprocedure status for the evaluation of complications

Complications

- Physiologic complications (more common)
 - Hypoxemia
 - Hypercapnia
 - Increase in ICP
 - Arrhythmias
 - Vagal stimulation related to inadequate topical anesthesia
 - Myocardial sensitization due to hypoxemia
 - Inadequate sedation may cause excessive catecholamine release.
 - Direct mechanical stimulation of the airway
 - Laryngospasm, bronchospasm, and a cough can induce arrhythmia.
 - Laryngospasm may occur even under general anesthesia.
- Mechanical complications (rare)
 - Pneumothorax
 - Bleeding (epistaxis is relatively common after the transnasal procedure)
 - Upper airway trauma in nonintubated patients
- Bacteriologic complications (rare)
 - 20% to 30% of patients will develop a transient fever following BAL (always self-limited).
 - Spreading infection from one area of the lung to another is possible.
 - Spilling of local pus into other airways
 - Bacterial endocarditis prophylaxis should be undertaken in patients with congenital heart defects.

OUTCOMES AND EVIDENCE

- Flexible bronchoscopy is an important tool in diagnosing and managing various pulmonary conditions in critically ill patients. Although special challenges exist for performing bronchoscopy in mechanically ventilated patients, if proper preprocedural training and planning are done and the patient is monitored carefully during the procedure, bronchoscopy can be performed quickly and safely at the bedside in most critically ill patients.
- Flexible bronchoscopy has a high diagnostic yield in immunocompromised patients with pulmonary infiltrates.
- Bronchoscopy has been shown to be effective in removing retained secretions and improving atelectasis.

THORACENTESIS AND THORACOSTOMY: BEFORE PROCEDURE

Indications

- Thoracostomy
 - Symptomatic pleural effusion
 - Large effusion
 - Respiratory compromise
 - Purulent effusion
 - Pneumothorax
 - Tension pneumothorax
 - Pneumothorax in a patient on positive ventilation with concern that the pneumothorax can develop tension
- Needle thoracocentesis
 - Emergent drainage of tension pneumothorax
 - Diagnosis of type of pleural effusion

Contraindications

- No absolute contraindications
- Small effusions may be too difficult to drain without risking injury to the lung
- Coagulopathy; relative contraindication; should be corrected prior to chest tube placement if the time allows

- Abnormal anatomy, such as scoliosis, may make the procedure riskier
- Overlying skin infection

Equipment

- For either procedure
 - 1% lidocaine local analgesia
 - Skin preparation, preferably with 2% chlorhexidine
 - Sterile towels and gloves
 - Syringes: slip tip for aspiration and with needles for lidocaine injection
 - Sterile container to receive pleural fluid sample
 - Bedside ultrasound, sterile sleeve, sterile ultrasound gel if ultrasound is to be used
- Thoracentesis
 - Styleted needle
 - Such as an IV catheter, which has the advantage that once the stylet is removed, the catheter remaining in the chest is soft and pliable
 - Gauge of the catheter depends on size of patient and viscosity of the fluid
 - For purulent fluid, a larger bore catheter is needed.
 - Length depends on the size of the patient.
 - Small infants and children: a catheter longer than 2 inches in length is rarely indicated.
 - Larger adolescents or obese children may need catheters 3 to 4 inches in length.
- Thoracostomy
 - Chest tube of appropriate size
 - Depending on the patient size and size of intercostal space
 - A larger chest tube is necessary for blood or purulent fluid
 - Smaller tube or pigtail-type catheter can be used if draining pneumothorax, transudative, or chylous fluid
 - Soft multiholed pigtail catheters are useful for draining transudative or chylous pleural effusions and simple pneumothoraces not associated with bronchopleural fistulae.
 - Connecting tubing
 - Drainage system
 - Pleur-Evac system with suction if draining a pneumothorax or a complex effusion or blood
 - Simple collection bag if transudative or chylous fluid
 - Steel needle, guide wire, and a dilator if using Seldinger technique

ANATOMY

For either procedure in any location, the needle should be advanced over the top of the rib and into the pleura to avoid injuring the intercostal vessels that run along the inferior aspect of each rib. For emergent needle drainage of a pneumothorax, the patient should be lying supine and the needle placed in the second or third intercostal space in the midclavicular line. For chest tube placement for pneumothoraces, it is preferable to use the fourth intercostal space in the midaxillary line. For drainage of effusions, the needle should be placed either along the midaxillary line or infrascapular where the fluid is greatest. Determining the optimal location for drainage of complex effusions that may be loculated is best done using ultrasound guidance. For the placement of the chest tube for large pleural effusions and pneumothoraces, the fourth intercostal space in the midaxillary line is also used.

The position of the patient for needle thoracentesis again depends on the location of the fluid and the age, size, and stability of the patient. An older child who is stable and cooperative can be seated during the procedure, allowing a posterior approach, which for most nonloculated effusions is optimal. However, unstable children, smaller infants, or any child who needs sedation should be placed in a supine or a slight decubitus position.

Ultrasound of the chest can be performed to identify the best location for draining the fluid, particularly if the fluid may be loculated,

either due to the fluid being purulent or the patient having had previous chest surgery or chest tubes. The ultrasound can be used just to “mark” the best location for drainage or can be used to guide the needle insertion.

PROCEDURE

- Sedation and analgesia: chest tube placement is particularly painful, and sedation and analgesia must be provided that are appropriate for the age and condition of the patient.
- Skin is prepared for the sterile procedure.
- A 1% lidocaine local analgesic is infiltrated using a small-gauge needle into the skin over the intercostal space to be used. Then, using a longer but still narrow-gauge needle, lidocaine is infiltrated into the subcutaneous tissue, intercostal muscle, and pleura. Care is taken to aspirate as the needle is advanced to avoid intravascular injection of the lidocaine.
 - Perform bedside ultrasound of the chest to evaluate fluid, noting the type of fluid (presence of fibrinous or bloody material) and the best location for insertion; ultrasound may be used for static determination of fluid or real-time guidance of needle insertion
- Needle thoracentesis
 - The catheter is then advanced through the numbed tissue using a slip-tip syringe to aspirate as the needle is advanced. When the needle passes through the pleura, there usually is a pop, as the pleura is a tougher tissue. Air or fluid is then able to be aspirated. The stylet in the needle can then be removed and the most supple catheter left in the pleura for further aspiration of either the tension pneumothorax or the effusion.
- Tube thoracostomy; two techniques are used
 - Standard cutdown technique
 - After instillation of the local analgesic, a small incision is made that will be slightly larger than the diameter of the chest tube.
 - Mosquito-type forceps are inserted through the incision and tunneled up one rib space and then rotated so that the points of the forceps are aimed toward the pleura.
 - They are then advanced over the superior aspect of the rib and through the pleura. Generally, the pleura will give, often with a pop.
 - The chest tube is then guided through the defect in the pleura and into the pleural space. Posterior placement of the chest tube is optimal for the drainage of fluid. Anterior placement, in a patient lying supine, is optimal for the drainage of a pneumothorax. Occasionally for patients with severe ongoing air leaks requiring prone and supine positioning, placement of anterior and posterior chest tubes may be needed to provide adequate continuous drainage of the pneumothorax.
 - The chest tube is secured with a suture and the incision closed with a purse-string closure, with the suture wrapped and tied around the chest tube.
 - The tube should also be secured to the child's side with either tape or a chest-tube-securing device (commercially available) to prevent the tube from being pulled out when the child becomes more active.
 - A clean dressing may be applied, but if the site is wet from ongoing drainage, a dressing need not be placed; the area can simply be kept clean and dry.
 - Seldinger technique
 - After instillation of local analgesia, a hollow needle is introduced into the pleural space while aspirating with a slip-tip syringe.
 - When air (in the case of a pneumothorax) or fluid (in the case of an effusion) is aspirated, the syringe is carefully removed, and the guide wire is passed into the pleural space. The wire should advance easily.

- Once the wire is in place, a small nick in the diameter of the chest tube is made in the skin at the needle entry point.
- The needle is removed, and the dilator passed over the wire and through the pleura; then the dilator is removed.
- The chest tube or pigtail catheter is then passed over the wire. The chest tube may need progressively larger dilators and should have a trocar in it to better advance the tube through the pleura. The wire and trocar are then removed.
- The tube or catheter is connected to the drainage system, sutured into place, and a dressing applied.

AFTER PROCEDURE

Postprocedure Care

- A postprocedure chest x-ray should be performed to document the chest tube location, resolution of the pneumothorax or effusion, and note any new problems related to the tube.
- If using a closed suction system, patency of the chest tube should be regularly assessed. Regular documentation of the amount of fluid removed should occur. The pigtail catheters may have to be flushed with heparinized saline to maintain patency.
- The dressing should remain dry or be replaced if not.

Complications

- Bleeding from the chest wall or lung can occur with or without coagulopathy.
- Intrapulmonary placement of the chest tube or lung laceration may occur with any technique.
 - Bronchopleural fistula may occur if the lung is punctured.
- Mechanical problems with the tube
 - Side holes being outside the pleural space
 - The tube itself being placed into the subcutaneous tissue and not the pleural space
 - Kinking of the tube
 - Occlusion of the tube with fluid or pus
- Failure of the drainage system, resulting in the reaccumulation of a pneumothorax
- Laceration of the heart, pulmonary artery, diaphragm, liver, or spleen

OUTCOMES AND EVIDENCE

- Thoracentesis is a safe, traditional means of removing pleural fluid for diagnosis and drainage.
- Thoracostomy can be safely performed in patients of any age and size.
- The Seldinger technique with the placement of a pigtail catheter can be used to drain either pneumothoraces or pleural effusions effectively.
 - In a retrospective review of chest tube placement in pediatric patients in an emergency department, it was noted that the pneumothoraces were all drained in both the pigtail group and the large-bore chest tube group. The patients in the pigtail group appeared to have less pain than the patients with standard chest tubes.
 - In another retrospective chart review of pediatric inpatients who had chest tubes placed, pigtails were noted to be as efficacious in draining serous and chylous pleural as standard chest tubes but less effective in the drainage of hemothoraces and not effective in draining purulent effusions.

PERICARDIOCENTESIS AND PERICARDIOSTOMY: BEFORE PROCEDURE

Indications

- Cardiac tamponade or impending tamponade due to a pericardial effusion or rarely, in small infants, pneumopericardium
- Rarely for the diagnostic drainage of a pericardial effusion

Contraindications

- When a cardiac tamponade is present, there is no contraindication.
- Relative contraindications
 - Coagulopathy
 - Inexperience of the operator
 - Loculation of the effusion
 - Loculation of the effusion where it cannot be reached percutaneously
 - Abnormal patient anatomy
- Certain situations may be better treated with open pericardiectomy and tube placement, such as the hemopericardium, particularly from penetrating trauma, purulent pericarditis, or loculated pericardial effusions with localized tamponade. However, if the patient is acutely in cardiac tamponade, pericardiocentesis can be performed while surgical pericardiectomy is being arranged.

Equipment

- Sedation: patient should be sedated for both comfort and safety to avoid inadvertent movement that could result in injury to the heart.
- Skin preparation
- Sterile gloves and towels
- 1% lidocaine local analgesia
- Hollow introducer needle
- Slip-tip syringe
- Flexible J guide wire that fits through the needle
- Dilator
- Pigtail catheter
- Connecting tubing, stopcock, collection bag
- Echocardiography equipment

ANATOMY

The patient is placed with the head elevated 30 degrees. The safest and easiest approach is the subxiphoid approach, although other approaches have been described. The needle is inserted at the junction of the xiphoid and the left costal margin and is directed toward the left shoulder.

PROCEDURE

- For emergent cardiac tamponade with or without cardiac arrest, blind needle aspiration with or without tube insertion is indicated.
- In less acute situations, echocardiographic assessment and direction are indicated
 - The pericardium is scanned to note the size and location of the fluid, presence or absence of loculated fluid, quality of fluid (whether there is evidence of blood or pus), and the presence of cardiac tamponade. Cardiac tamponade is diagnosed by the

collapse of the right atrial wall, diastolic compression of the right ventricle, abnormal tricuspid and mitral flow velocities with inspiration, and dilated inferior vena cava with the lack of a collapse during inspiration.

- The patient is placed on a cardiac monitor to watch for arrhythmias.
- The skin is sterilely prepped and draped.
- Lidocaine 1% local analgesia is infiltrated in the skin subxiphoid and then directed toward the lower left costal margin, being careful to aspirate prior to injection.
- The needle is then advanced from the subxiphoid position toward the left costal margin and the left shoulder, aspirating as the needle is advanced.
 - When fluid is obtained, the needle is no longer advanced.
 - If the fluid is bloody, place some of the fluid on a sterile gauze.
 - If the fluid clots, it is likely that the heart has been entered.
 - If the fluid does not clot, the fluid is likely a hemorrhagic effusion from the pericardial sac.
 - The echocardiogram may be used to note the position of the needle. Additionally, a small amount of saline can be injected through the needle, and microbubbles will be detected in the pericardial space if the needle is in a good position.
- The syringe is carefully removed, and the J-type wire is passed through the needle; its position in the pericardium is confirmed with the echocardiogram.
- A small nick is made in the skin the diameter of the catheter.
- The needle is removed, leaving the wire in the pericardial space, and the dilator is passed over the wire. Again, the wire position is confirmed with the echocardiogram.
- The dilator is then removed, and the catheter is passed over the wire; the position is again confirmed echocardiographically.
- The wire is removed and the stopcock and tubing connected to the catheter. The catheter is then aspirated.
- The catheter is secured with a suture, and the site sterilely dressed.

AFTER PROCEDURE

Postprocedure Care

- The catheter should be allowed to drain passively into a collection bag. The patency of the catheter should be checked, and if determined not to be patent, a small amount of sterile heparinized saline can be injected into the catheter to clear any clots or fibrin debris.
- The dressing should be changed according to the CVL dressing standard.

Complications

- Myocardial perforation may occur but may not result in any significant injury if the ventricle is entered. However, a laceration can occur, resulting in bleeding into the pericardial sac, causing or worsening tamponade.
- Coronary laceration is a rare occurrence and can result in acute cardiac ischemia and may require emergent operative intervention. It can be associated with death.
- Entering the pleural space can occur and thus a risk of pneumothorax or hemothorax.
- Injury to the diaphragm and abdominal viscera can occur, as well as pneumoperitoneum or hemoperitoneum.

OUTCOMES AND EVIDENCE

- Percutaneous drainage of pericardial effusion can be safely performed in children.
- Echocardiographic guidance improves both the success and safety of the procedure.

- In a data analysis of a prospective echocardiography database of adults, pericardiocentesis performed for tamponade was successful in relieving tamponade in 99% of patients and was the definitive therapy in 82%, with only a 3% incidence of complications.
- Similar studies in pediatric patients are not available.

INTRACRANIAL PRESSURE MONITORING: BEFORE PROCEDURE

Indications

- Cerebral edema
- Traumatic brain injury (TBI)
- Glasgow Coma Scale (GCS) score less than 8
- May be indicated in patients with evidence of TBI and a better GCS if they will not be able to have their neurologic exam followed; for example
 - During anesthesia for another procedure
 - If the patient must be kept sedated for other reasons (e.g., severe lung injury with high ventilator settings)
- Medical causes
 - Medical encephalopathies (e.g., diabetic ketoacidosis and Reye syndrome)
 - Meningitis or encephalitis with evidence of cerebral edema
- The use of ICP monitoring in global hypoxic-ischemic injury (e.g., near-drowning after prolonged cardiac arrest) is less useful and may not be indicated.

Contraindications

- Coagulopathy is thought to be an absolute contraindication.
- Massive cerebral edema with slit-like ventricles may not allow the placement of an intraventricular device but will allow a tissue pressure monitor.

Equipment

- The available monitoring systems are discussed in detail in Chapter E20 of the textbook on the central nervous system monitoring in adults. Specific pediatric data on the advantages or disadvantages of these systems are lacking.

ANATOMY

Refer to Chapter E20; same landmarks as an adult.

■ PROCEDURE

- Should be performed by a neurosurgeon skilled in pediatric care
- Sedation and analgesia should be provided that is appropriate for the patient's age and clinical condition.
- Preparation and procedure guidelines are the same as adult placement.

■ AFTER PROCEDURE

Postprocedure Care

- With the head of the patient elevated at 30 to 45 degrees, the zero reference point for the particular ICP monitoring system should be placed at the outer canthus of the patient's eye.
- The ICP monitor must be transduced at all times. Tissue monitors can only be zeroed at the time of insertion. Intracranial monitors can regularly be zeroed and should be zeroed at least every 12 hours.
- The drip chamber of the ICP monitors will be at the level designated by the physician for optimal CSF drainage. For patients with increased ICP, some CSF should drain, but too rapid drainage can result in ventricular collapse and herniation.
- For pressure readings, the system must be off for drainage and open to the patient.
- Components of the system should not be replaced unless a new ICP system is placed or if the components become contaminated.

Complications

- Intracranial infection; most common but still relatively uncommon
- Intracerebral hemorrhage, especially if coagulopathy exists or develops with a monitor in place; may occur at the insertion or over time; may be intraparenchymal or intraventricular
- CSF leakage
- Blockage of pressure monitoring with blood or tissue

■ OUTCOMES AND EVIDENCE

- Increased ICP is associated with decreased survival and poor neurologic outcome. It may be difficult to diagnose in pediatric patients, especially the extent of the increased pressure, so monitoring is warranted.
- Multiple studies, as well as consensus practice, have shown that aggressive management of increased ICP after TBI may reduce secondary brain injury in both adults and pediatric patients.
- Since the widespread use of ICP monitoring, no randomized controlled trial in patients with TBI would be possible.
- In a study comparing the Camino tissue monitor with intraventricular pressure monitor in pediatric patients, there was a good correlation between the two measurements in the same patient on the same day.
- In a prospective uncontrolled study of complications of tissue pressure monitors in pediatric patients, 7% developed positive tip cultures (risk increased with length of monitoring), and 13% developed loss of waveform, but overall the monitors were safe, especially when used for less than 7 days.
